### Diagnostic Testing

In patients with third trimester bleeding, ultrasonography may be performed to rule out placenta previa, to determine fetal age and viability, and to look for placental abruption. However, only 25% to 50% of placental abruptions are identified on ultrasound, and the appearance may be unimpressive because the clot looks similar to the placenta. When abruption is seen on ultrasound, its specificity is 95%. The diagnosis of placental abruption is clinical, and the emergency physician should suspect placental abruption in a pregnant woman with significant uterine contractions and fetal distress. Monitoring of the fetal heart rate and uterine contraction (tocography) should be initiated early. The diagnosis is confirmed by examination of the placenta after delivery.

In trauma patients with abdominal pain in late pregnancy, other injuries must be considered and are best managed by a multispecialty team consisting of emergency medicine, trauma, and obstetrics. Early evaluation with focused assessment with sonography for trauma (FAST), as well as assessment of fetal size (for dates) and fetal heart rate, is key. Chest and pelvis radiographs, as well as computed tomography (CT) scans, may be necessary. Though not the test of choice for abruption, abdominal CT scans have a sensitivity of 50% to 100%, depending on the expertise of the radiologist.

During the evaluation it is important that the fetus be monitored continuously as early as possible. Resuscitation of the mother is the best treatment for the fetus. If the mother has loss of vital signs, perimortem cesarean section should be considered. See Chapter 11, Resuscitation in Pregnancy; Chapter 79, Blunt Abdominal Trauma; and Chapter 122, Emergency Delivery and Peripartum Emergencies, for further details.

Laboratory evaluation includes a complete blood count, comprehensive metabolic profile, PT and PTT, DIC panel (fibrinogen, fibrin split products), urinalysis, and blood type and crossmatch. Anemia is a concern with both placental abruption and placenta previa. Because DIC can complicate placental abruption, it is important to perform the relevant tests. The Kleihauer-Betke test, which confirms the presence of fetal blood cells in the maternal circulation, may be performed if fetal-maternal transfusion is suspected. It is neither sensitive nor specific for abruption but quantifies that volume of fetal-to-maternal transfusion if positive.

### Treatment

Basic management of vaginal bleeding in third trimester pregnancy includes determination of the hemodynamic status of the mother and resuscitation as needed, assessment of fetal condition and age by fetal monitoring and ultrasonography, and decision making about the optimal timing of delivery. Early consultation with obstetrics colleagues is critical.

The patient should be placed on her left side to increase venous return. Initial management of significant vaginal bleeding is volume resuscitation and transfusion as needed. Although normal vital signs are optimal, they may be falsely reassuring because of the physiologic increase in maternal volume. After stabilization of the mother is ensured, the status of the fetus is assessed with continuous monitoring and ultrasound imaging to determine viability and age. The fetal heart rate may be a good indicator of maternal status; however, it is not specific.

Ultrasoundography will diagnose placenta previa, which is managed by delaying delivery if the patient is stable and the fetus is premature. If there is heavy bleeding or the pregnancy is near term, delivery should be undertaken by cesarean section, regardless of fetal viability.
Management of placental abruption is contingent on the viability or distress of the fetus. In cases of mild placental abruption without fetal distress and severe placental abruption with fetal mortality, infants are delivered vaginally. In cases of moderate placental abruption with fetal distress, cesarean section is preferred.

**RED FLAGS**

**Third Trimester Bleeding**

Hypertension not only increases the risk for placental abruption but also predisposes to more severe placental abruption and increased fetal mortality.

Although vaginal bleeding occurs in 80% of cases of placental abruption, some abruptions are concealed, with no evidence of overt bleeding.

Placental abruption in patients seen in the emergency department may be the result of abuse.

Many women with vaginal bleeding will have brief painless bleeding initially; this is a sign of placenta previa.

Rh-negative women should be given 300 units of RhoGAM. This dose is adequate to prevent maternal sensitization to up to 15 mL of fetal blood. A larger dose may be necessary if fetal-to-maternal transfusion is greater as determined by the Kleihauer-Betke test.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Women with vaginal bleeding late in pregnancy need to be admitted. If the hospital does not have critical obstetrics and neonatal care facilities, transfer to a tertiary hospital is required.

Emergency Delivery and Peripartum Emergencies

Jeremy B. Branzetti

**KEY POINTS**

- If shoulder dystocia is encountered, attempt the McRoberts maneuver with suprapubic pressure while simultaneously calling for obstetric assistance.
- Practitioners underestimate blood loss in postpartum hemorrhage by as much as 50%.
- Uterine inversion is relatively uncommon but is associated with significant morbidity if not recognized and treated promptly.
- Up to 87% of patients with uterine rupture have no pain, and up to 89% have no vaginal bleeding.
- Perimortem cesarean delivery is indicated in gravid patients if more than 24 weeks pregnant and if arrest continues after 4 to 5 minutes of cardiopulmonary resuscitation.
- The clinical examination of a term pregnant patient is notoriously unreliable.
- Treatment of anaphylactoid syndrome of pregnancy is similar to that for sepsis and disseminated intravascular coagulation and should begin immediately; the diagnosis is one of exclusion, and patients must be treated promptly to survive.

**PRESENTING SIGNS AND SYMPTOMS**

Labor is classically heralded by shedding of the mucous plug that was occluding the cervix (the “bloody show”), passage of clear fluid from the vagina from ruptured membranes (the “water breaking”), and contractions. True contractions are organized and detectable by tocometry; tend to increase in pain, frequency, and strength with time; and have associated cervical changes. Braxton-Hicks contractions, commonly called false labor, are characterized by unorganized myometrial activity without cervical changes. Other common symptoms at labor onset include abdominal pain and back pain.

In the emergency department (ED), the majority of patients seen in labor are in the latter part of stage I or stage II.1 Precipitous delivery is a common occurrence because most patients whose labor progresses more slowly will have time to get to their designated obstetric facility.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

For any woman encountered after 20 weeks of pregnancy, labor must be in the differential diagnosis. Although the ultimate differentiation of false labor, or Braxton-Hicks contractions, is made by continuous tocometry, a good history can often make the diagnosis.

For patients with a chief complaint of vaginal bleeding, placental abruption and placenta previa should be considered. When the only complaint is passage of clear fluid from the vagina, premature rupture of membranes (PROM) and preterm premature rupture of membranes (PPROM) should be assumed until proved otherwise.

For an uncomplicated delivery, no diagnostic testing is needed. In those without any prenatal care, a complete blood count and Rh status should be obtained.

For patients complaining of vaginal bleeding, placenta previa or abruption should be assumed. Ultrasound is required to evaluate for previa. It is essential that placenta previa be diagnosed early because vaginal delivery is absolutely contraindicated with this condition. Ultrasound is not useful in ruling out the diagnosis of placental abruption because toco-cardiographic monitoring in an obstetric suite is required.

**TREATMENT**

The major point of triage is during stage I of labor. If care is available in-house, transfer can be accomplished at any point before crowning. If care requires out-of-hospital transfer, it is imperative to establish early and reliable contact with the treating obstetrician to facilitate a safe plan of care.

---

**EMERGENCY DELIVERY**

**PATHOPHYSIOLOGY**

During labor the fetus follows a series of stereotypic movements known as the cardinal movements of labor. Although the specifics have little bearing on the emergency physician’s approach to labor, the final movement typically leaves the baby with the occiput anterior (relative to the maternal pelvis) and the head sharply flexed. This position offers the smallest fetal head diameter and is therefore optimal for passage through the pelvis. Any deviation from this position is by definition a malpresentation, and these different presentations are all associated with increasing morbidity and mortality. The overwhelming majority of births, however, will require little physician intervention beyond timely encouragement and vigilance for complications.

For a description of potential malpresentation, along with management recommendations, see www.expertconsult.com
Even though multiple physical interventions may be necessary with an abnormal delivery, an uncomplicated one typically only requires measures that support smooth fetal passage. Resuscitation equipment should be available immediately. Episiotomies are no longer recommended during routine pregnancies. They should be used sparingly and typically only with complicated deliveries. If shoulder dystocia is encountered, hyperflexion of the maternal hips and knees (McRoberts maneuver) and suprapubic pressure are first-line interventions that resolve most instances of dystocia.

After determination of hemodynamic stability, the next priorities are to determine whether true labor is occurring and the appropriate disposition to achieve optimal medical care. For any patient with a complaint of passage of clear fluid from the vagina without other signs and symptoms of labor (bloody show and regular, progressing, often painful contractions), a sterile speculum examination should be performed before a gloved digital examination to evaluate for PROM.

Once labor is confirmed, the goal is to evaluate the positioning (orientation in space relative to the maternal pelvis) and presentation (body part palpable at the cervix) of the fetus, along with the degree of change in the uterine cervix. This includes assessment of station (level of decent into the pelvis relative to the maternal ischial spines), effacement (degree of cervical thinning), and dilation of the cervical aperture. For the emergency physician, determination of dilation and effacement is the most important part of the examination—a fetus that is still contained within a closed and minimally effaced cervix will probably be transferred to obstetrics whether or not it is vertex (fetal head as the presenting part).

If delivery is imminent, the patient will have to remain in the ED. A gynecologic bed with lithotomy position capability is ideal, and a resuscitation bay with greater accessibility and equipment is recommended. A radiant warmer and appropriate airway equipment should be available. Positioning of the mother may require an approximate 10-degree tilt to the left to prevent uterine pressure on the inferior vena cava and associated hypotension. When crowning occurs, the mother should be instructed to push along with the contractions, with the physician positioned in front of the introitus ready to accept the fetus. As soon as the head is accessible, continuous gentle countertraction should be administered to maintain it in a flexed position. This technique provides control of an explosive delivery, as well as avoidance of the high morbidity associated with fetal neck hyperextension. Though once recommended, the modified Ritgen maneuver has recently been shown to be associated with an increased rate of third-degree lacerations and episiotomy in comparison with a “hands-off” approach. Similar rates of perineal tears were found for each modality. When the head is clear, the fetus rotates 90 degrees. Suction of the fetal mouth and nose should be performed as soon as possible in the setting of meconium staining. Typically, the shoulders will then be delivered, anterior first, without assistance. Mild downward traction on the torso (not lateral flexion of the neck) may be required to assist passage of the anterior shoulder. Once clear, the posterior shoulder is typically delivered spontaneously or with upward traction in a similar manner as just described. At this point the largest fetal diameter has passed, and labor is generally smooth. The cord may be clamped once it is accessible after passage of the fetus. If the cord is tightly wound around the fetus, knotted, or abnormal in any way, it is clamped (typically at 7 and 10 cm) and cut once accessible. When free, the neonate is dried and warmed and its resuscitation needs evaluated. If available, a neonatologist should be present at any ED delivery.

Three classic signs indicate delivery of the placenta: sudden lengthening of the cord, a gush of blood, and a change in the shape of the uterine fundus. Once the fetus is clear, gentle traction on the cord should continue until these signs are seen. After the placenta is delivered, typically within 20 minutes, it is inspected for irregularities that may suggest retained tissue. Manual abdominal massage of the uterus fundus will often assist in uterine contraction. An infusion of oxytocin, typically 20 units in a 1000-mL bag of normal saline infused at about 200 mL/hr, can be administered to hasten separation and assist in contraction of the uterus back into the pelvis.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

After the placenta is delivered and the neonate is stabilized, the mother should be evaluated for bleeding—the causes and treatment of which are covered next. If hemodynamically stable after the first postpartum hour, the mother may be transferred to the postpartum floor.

**POSTPARTUM HEMORRHAGE**

**EPIDEMIOLOGY**

Hemorrhage is a significant cause of maternal morbidity and is the second most common cause of peripartum deaths (following amniotic fluid embolism). Hemorrhage was a direct cause of more than 18% of 3201 pregnancy-related maternal deaths in the United States from 1991 to 1997. Worldwide, hemorrhage has been identified as the single most important cause of maternal death and is responsible for almost half of all postpartum deaths in developing countries.

Postpartum hemorrhage is the term used to describe excessive blood loss after delivery. Classically, it is defined as more than 500 mL of blood loss in a vaginal delivery or more than 1000 mL of blood loss in a cesarean delivery; however, careful quantitative measures reveal that blood loss in the range of 500 to 1000 mL is actually average for both types of delivery. Of note, practitioners often underestimate blood loss by as much as 50%. For the ED physician, the most important causes of hemorrhage in the postpartum period are birth trauma, uterine atony, uterine rupture, and uterine inversion.

**PATHOPHYSIOLOGY**

Separation and delivery of the placenta constitute the third stage of labor. With separation of the placenta, there is also
severance of the numerous uterine arteries and veins that carry 600 mL/min of blood through the intervillous space. The most important factor for hemostasis is contraction and retraction of the myometrium to compress and obliterate the open lumens of the vessels.

Uterine atony, the most common cause of postpartum hemorrhage, is the result of a hypotonic uterus after delivery. Factors that lead to uterine overdistention or that interfere with uterine contractility can cause uterine atony and are associated with postpartum hemorrhage. Although it is important to keep these associations in mind, most cases of postpartum hemorrhage occur without any known predisposing factors.

Trauma to the genital tract during labor and delivery (lacerations of the perineum, vagina, vulva, or cervix) is the second most common cause of postpartum hemorrhage. Abnormal placentation (placenta accreta, increta, or percreta) can contribute to postpartum hemorrhage in different ways: (1) an adherent placenta or large blood clots prevent effective contraction of the myometrium, thereby impairing hemostasis at the implantation site, and (2) significant bleeding from the implantation site is more likely with placental separation of abnormally adherent tissue.

Uterine inversion is prolapse of the uterine corpus to or through the cervix. Uterine inversion may be incomplete (inverted but does not go through the cervix) or complete (the fundus protrudes through the cervix). In the more extreme cases, the entire uterus may prolapse out of the vagina. Most cases are acute and occur immediately after delivery and before the cervical ring constricts. If inversion occurs (or is noted) after cervical contraction, the inversion is termed subacute. Chronic inversion takes place weeks after delivery. The majority of cases of uterine inversion occur as a result of traction on the umbilical cord during removal of the placenta. Acute, significant hypotension is common.

Uterine rupture is classified by the degree (complete or incomplete) and cause (spontaneous or traumatic) of the defect. A complete uterine rupture is defined as a full-thickness tear of the uterine wall and overlying serosa; it is associated with life-threatening maternal and fetal compromise. After complete rupture, the uterine contents may escape or partially extrude from the uterus and into the peritoneal cavity. An incomplete uterine rupture is defined as uterine muscle separation with an intact visceral peritoneum (often from uterine scar dehiscence). In an incomplete rupture, hemorrhage frequently extends into the broad ligament, which has a tamponading effect.

**PRESENTING SIGNS AND SYMPTOMS**

Peripartum patients may lose a substantial amount of blood before becoming hypotensive or feeling symptomatic. Immediate postpartum hemorrhage should be recognized as a potential complication of a precipitous delivery. The classic clinical manifestation is a woman with sudden massive vaginal bleeding who is tachycardic, pale, and possibly diaphoretic or hypotensive. However, three factors make this classic manifestation flawed. First, an elevated pulse and decreased blood pressure are insensitive indicators until large amounts of blood have been lost. Second, many patients will have steady bleeding that, although moderate in appearance, may escape notice until serious hypovolemia develops. Third, intrauterine, intravaginal, intraperitoneal, and retroperitoneal accumulation of blood can be overlooked.

In a reported case series on uterine inversion, the most common signs were shock and hemorrhage. With a complete inversion, the prolapsed uterus may be visible as a large, dark red polypoid mass within the vagina or protruding through the introitus. If the fundus remains within the vagina, the diagnosis may be suspected because of dimpling, indentation, or absence of the uterine fundus on abdominal examination or because a mass is palpated in the cervix on bimanual examination. Establishing the diagnosis of incomplete inversion can be quite difficult; severe hypotension, postpartum hemorrhage, and subtle abnormalities on abdominal examination may be the only clues.

Uterine rupture is also a difficult clinical diagnosis and should be considered in any patient with unexplained peripartum hemorrhage or hypotension. The classic findings of uterine rupture are “ripping” or “tearing,” suprapubic pain and tenderness, absence of fetal heart sounds, recession of the presenting parts, and vaginal hemorrhage. Signs and symptoms of hypovolemic shock and hemoperitoneum may follow. This classic manifestation is actually rare; 87% of patients with uterine rupture have no pain and 89% have no vaginal bleeding. Pain is also an unreliable finding because of the altered response to noxious intraperitoneal stimuli by a stretched abdominal wall. Fetal distress is the most consistent finding (80% to 100%), with fetal bradycardia being the most common sign. Most reports of uterine rupture describe patients with normal blood pressure or even elevated blood pressure without tachycardia. Abnormal maternal vital signs are late indicators of severe hemorrhage. The most important risk factor for uterine rupture is a previous uterine scar; other factors are listed in **Box 122.1**.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Postpartum hemorrhage is a sign, not a diagnosis; it is important to consider the cause of the postpartum hemorrhage because it will often direct the treatment. The key to identifying the cause of postpartum hemorrhage is the physical examination. Because uterine atony is the most common cause of postpartum hemorrhage, accurate assessment of uterine tone is essential. To assess uterine tone, a hand is placed on the anterior wall of the uterus (over the fundus) to palpate it. If a soft, boggy, or very large uterus is felt, the diagnosis of uterine atony is established. At this point, management of uterine atony should be a priority over inspection for secondary causes of bleeding. If a firm, contracted uterus is felt, a search for other causes should be initiated promptly.

Without palpation or visualization of a frankly prolapsed uterus, it may be difficult to differentiate uterine inversion from severe atony. Heavy bleeding may make visualization of the cervix impractical. In addition, accurate abdominal palpation for a uterine fundus may be impossible in an obese patient. Depending on factors such as patient stability, resources, and diagnostic uncertainty, ultrasonography or laparotomy may be necessary. In stable patients in whom the diagnosis is uncertain and resources are available, prompt ultrasound scanning may be helpful. Ultrasonography may be able to identify retained products or clot in the uterus, but manual exploration is still needed. Ultrasound can also help detect peritoneal free fluid suggestive of uterine rupture. In selected circumstances in stable patients, a computed tomography scan can be useful in making the diagnosis in those with postpartum hemorrhage (retroperitoneal hematoma). If the accompanying hemorrhage or shock is sufficiently alarming to require immediate exploration, the correct diagnosis may be established only at laparotomy.

Although congenital coagulation defects may be relatively rare, consumptive, dilutional, and disseminated intravascular coagulopathies are important considerations. Depletion of platelets and soluble clotting factors after blood loss and subsequent crystalloid and packed red blood cell replacement is difficult to distinguish clinically from disseminated intravascular coagulopathy. Placental abruption, amniotic fluid embolism, HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count), and intrauterine demise are pregnancy-related risk factors for disseminated intravascular coagulation. Initial laboratory studies include a complete blood count, coagulation studies, disseminated intravascular coagulation panel, liver function tests, and basic metabolic panel.

TREATMENT

The most important aspects of managing postpartum hemorrhage are obtaining hemostasis and treating shock, including supplemental oxygen, placement of two large-bore intravenous (IV) lines, hemodynamic monitoring, and volume replacement. In addition, blood should be typed and cross-matched and 4 to 6 units of packed red blood cells should be available. Consultation with the obstetrics service should be arranged. Along with the initial resuscitation, bimanual massage and IV oxytocin should be initiated (Fig. 122.1 and Table 122.1). A Foley catheter should be placed.

If the placenta has been delivered, manual uterine exploration may reveal uterine rupture or retained products or clots (which should be removed manually to improve uterine contraction). If the placenta is still in place and bleeding is ongoing, the placenta should be removed if a distinct cleavage plane is palpated on exploration. If an indistinct cleavage plane is revealed, the diagnosis of placenta accreta is likely. In this case the placenta should not be removed in the ED. Bimanual uterine compression should continue, with the goal being to stabilize patients until they can be taken to the operating room.

Trauma to the genital tract can be diagnosed by careful inspection of the labia, vagina, and cervix for laceration or hematoma. Noncomplex (first or second degree), easily accessible lacerations can be repaired with absorbable suture. Cervical lacerations and third- and fourth-degree lacerations should be repaired by an obstetrician. Temporary hemostasis may be achieved by direct pressure or, in the case of cervical lacerations, by gentle application of ring forceps to the bleeding point.

Retroperitoneal hematoma is a potentially life-threatening condition that may be manifested as hypotension, cardiovascular shock, or flank pain. Once a diagnosis is made, treatment should be supportive until the obstetrician, interventional radiology, or the operating room is available.

First-line interventions for atony are part of the initial management of postpartum hemorrhage—namely, initiation of bimanual uterine compression, IV oxytocin, and clearing of products of conception and clots from the uterus. If bleeding persists after the initial interventions, additional uterotonic medications should be given (see Table 122.1). The choice of agent may be influenced by the side effect profile, but the best drug is probably the agent that is the most quickly available in the ED. Interventional radiology may be beneficial because embolization may control the bleeding. In any case, temporizing measures may be required until definitive intervention (Table 122.2).

Uterine tamponade with sterile gauze and balloon tamponade are commonly used temporizing measures. Uterine balloon tamponade has been described with large Foley catheters, Sengstaken-Blakemore tubes, condom catheters, sterile gloves, and Rusch urologic catheters, as well as with catheters specifically designed to be used for uterine tamponade in patients with postpartum hemorrhage (SOS Bakri tamponade balloon).10

UTERINE INVERSION

Management of uterine inversion has two important components: treatment of hemorrhagic shock and immediate reposi-
tioning of the uterus (Fig. 122.2). Resuscitation should be initiated immediately and continued while attempts are made to reposition the uterus manually. If oxytocin is being infused, it should be stopped once uterine inversion is suspected.

The success of nonsurgical replacement depends on completion before the myometrium regains its tone. The reported rate of successful immediate reduction is between 40% and 80%.11 If initial measures are delayed or fail to relieve the condition, the inversion may progress to the point at which operative treatment or even hysterectomy is necessary.

The most common nonsurgical replacement method is a variation of the Johnson maneuver.12 The prolapsed uterus is
Fig. 122.1 Algorithm for postpartum hemorrhage management strategies. ABCs, Airway, breathing, and circulation; AFE, amniotic fluid embolism; CT, computed tomography; CV, cardiovascular; DIC, disseminated intravascular coagulation; IR, interventional radiology; OB, obstetrics; OR, operating room; UI, uterine inversion; UR, uterine rupture.
cupped in the operator’s palm, and firm upward pressure is applied to move the uterus up through the cervix along the natural curve of the pelvis toward the umbilicus until it is in place. Usually when the inverted mass is pushed upward, the uterus automatically reverts, with the fundus returning to its anatomic position. If the placenta has not separated, it should not be removed.

If initial repositioning is unsuccessful, myometrial relaxation with pharmacologic agents should be attempted. Magnesium sulfate, terbutaline, and nitroglycerin (attractive because of its easy availability and short half-life) are the agents most commonly used (see Table 122.1). Attempts at manual repositioning of the uterus should continue.

After successful reduction, the uterus should be supported for several minutes to allow the ligaments to return to their original state while uterotonics are administered. If magnesium sulfate was administered as a tocolytic, calcium gluconate can be given to reverse the tocolytic effect. Fluid and blood replacement and manual uterine massage should be maintained until the uterus is well contracted and the bleeding has stopped. Antibiotics should be started as soon as practical. Uterotonics are continued for at least 24 hours.

If all other efforts have failed to reposition the inverted uterus, operative intervention is required. If the uterus was repositioned with the placenta attached, manual removal can be attempted once the use of relaxants is stopped. Uterotonics are continued for at least 24 hours. Antibiotics should be started as soon as practical. Uterotonics are continued for at least 24 hours.

**UTERINE RUPTURE**

Initial management of uterine rupture differs and is based on the stability of the patient and fetus. Because the results of examination are normal in most patients with uterine rupture and because fetal distress is the most common finding, initial management will probably be the same as that for other causes of acute fetal distress—urgent delivery.

The physician should consult obstetrics on an emergency basis, ensure adequate IV access, notify the blood bank, and alert the neonatal team to be ready for intensive care newborn care.

resuscitation. If these resources are not available in the hospital, arrangements should be made for immediate transfer.

For unstable patients, prompt, aggressive resuscitation is an important temporizing measure until definitive surgical repair is performed. Fetal morbidity almost invariably occurs because of catastrophic hemorrhage, fetal anoxia, or both. In a study of 99 cases of uterine rupture, the best fetal outcomes were noted when surgical delivery was accomplished within 17 minutes from the onset of fetal distress.7

If the patient is stable, no signs of fetal distress are present, or the diagnosis is unclear, ultrasonography can be useful. Ultrasound findings include lack of normal orientation, uncertain placental location, fetal demise, and absence of amniotic fluid.

### FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Obstetric consultation should be obtained on an emergency basis to assist in the delivery and postpartum care of the mother, as well as pediatric or neonatal services for the newborn. All patients who deliver in the ED should be admitted to an obstetric floor after delivery or stabilization of the acute complication.

**PERIMORTEM CESAREAN DELIVERY**

**Epidemiology**

Maternal arrest is estimated to occur in 1 in 4000 to 6500 pregnancies in the United States.14-16 In any maternal arrest that occurs beyond 24 weeks’ gestation, perimortem cesarean delivery should be considered as a potentially lifesaving intervention for both the mother and the fetus.17

When comparing causes of death in the cohort of women undergoing perimortem cesarean delivery with all maternal deaths, trauma accounts for a larger proportion in the former group.18 Perimortem cesarean delivery is one of the oldest
caesare”—consequently the name cesarean operation. The first documented maternal survival after cesarean delivery was a Swiss woman sectioned by her husband in 1500.

**PATHOPHYSIOLOGY**

Even under ideal conditions, cardiac output from chest compressions in a gravid patient is about 10% of normal. Cardiac output can be improved by displacing the uterus or tilting the patient (left lateral decubitus position); however, a decrease in effective chest compressions occurs with an increase in the patient’s body tilt.20

Fetal outcomes are most directly related to the time from maternal arrest to delivery. Other important variables are the maturity of the fetus, the performance and effectiveness of maternal cardiopulmonary resuscitation, the cause of the maternal arrest, and the availability of a neonatal intensive care unit (NICU).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Perimortem cesarean delivery is indicated for gravid patients more than 24 weeks pregnant (or the uterine fundus is four...
AMNIOTIC FLUID EMBOLISM

Epidemiology

Amniotic fluid embolism and the resulting anaphylactoid syndrome of pregnancy occur in late pregnancy or immediately postpartum. Though rare (roughly 1 in 8000 to 80,000 pregnancies), it is responsible for about 10% of all maternal deaths in the United States and is the most common cause of peripartum death.\(^\text{22}\)

Pathophysiology

Despite knowledge of this deadly syndrome for more than 80 years, its cause and pathophysiology are not fully understood. The criteria to make the diagnosis are still controversial, and no management interventions have been proved to improve outcomes or prevent the syndrome.\(^\text{23}\) The term amniotic syndrome of pregnancy is considered more appropriate than the term amniotic fluid embolism because of lack of evidence supporting a causative embolic event.\(^\text{24}\)

Anaphylactoid syndrome of pregnancy, from a clinical, hemodynamic, and hematologic standpoint, is similar to anaphylaxis and septic shock and suggests the possibility of a shared pathophysiologic mechanism.\(^\text{25}\) The syndrome appears to be initiated after maternal intravascular exposure to fetal tissue. Fetal-maternal tissue transfer is common and probably normal. It is proposed that when fetal antigens breach a maternal immunologic barrier in some women, release of endogenous mediators is triggered, and an anaphylactoid syndrome can occur.\(^\text{26}\)

Neurologic damage is seen in as many as 85% of survivors of anaphylactoid syndrome.\(^\text{25}\) The mechanism of neurologic injury is thought to be severe hypoxia leading to encephalopathy and seizures. The increased metabolic demand concurrent with seizures (seen in 50%) may worsen the brain injury, especially in the setting of hypoxia.\(^\text{3}\) Disseminated intravascular coagulation developed within 4 hours of initial evaluation in more than 80% of patients.\(^\text{25}\) If diffuse bleeding occurs, hemorrhagic shock can contribute to the hypotension.

Presenting Signs and Symptoms

The classic manifestation of anaphylactoid syndrome of pregnancy is acute hypoxia or respiratory arrest with associated cardiovascular failure, altered mental status, seizures, and coagulopathy in the immediate peripartum period. It typically occurs abruptly and with catastrophic outcomes, but less severe forms of this syndrome have been described. In about 10% of patients the diagnosis is made postpartum, and it has been diagnosed as late as 48 hours postpartum.

Differential Diagnosis and Medical Decision Making

The National Registry’s criteria for the diagnosis of amniotic fluid embolism are included in Box 122.3. The diagnosis of

Fig. 122.3 Perimortem cesarean delivery: fetal outcomes in relation to time interval from maternal arrest to delivery.

TREATMENT

See Box 122.2, “Procedure for Perimortem Cesarean Delivery,” and Fig. 122.3.
anaphylactoid syndrome of pregnancy is one of exclusion. Its dramatic and rapid onset should prompt immediate action; death has been reported in 30 minutes to 7 hours after onset, with most deaths occurring within the first 2 hours. The initial signs and symptoms can be difficult to differentiate from those seen with other serious causes, but management, with a focus on cardiopulmonary stabilization, is similar (Box 122.4).

**REFERENCES**

References can be found on Expert Consult @ www.expertconsult.com.
Excluding nuchal cord, breech presentation is the most common malpresentation of the fetus. It complicates 4% of all births with a bias toward premature, low-birth-weight infants. Frank breech is the most common, followed by footling and complete. Prolapsed umbilical cord is a dreaded complication of breech presentation and was demonstrated to be a negligible risk with frank breeches, occurring about 5% to 6% of the time with complete breeches, and had an alarming incidence of 15% to 20% with footling breeches.26

Breech presentation is typically divided into complete (hips and knees flexed), frank (hips flexed, knees extended), and incomplete (one or both hips extended, termed foottling). Prematurity and congenital defects are the primary risk factors associated with breech presentations. Because of the abnormal presenting body part, the cervical aperture may not be fully occluded, which can allow the cord to potentially prolapse and entangle with the fetus at any point after membrane rupture. Alternatively, a nuchal arm may occur in which the fetal arm is entrapped posterior to the neck. This complication may result in fracture of the clavicle or humerus, brachial plexus injury, or hypoxic insult from entrapment of the fetal head. The other nonvertex presentations include face, brow, and transverse lie. In a face presentation the fetal head is in full extension. A brow presentation is midway between this and vertex. A transverse lie is an instance in which the fetal pole is transverse relative to the maternal pelvis, a situation likely to never be seen by an ED physician given the impossibility of delivering a fetus in this position.

The differential diagnosis for fetal malpresentation includes breech (as well as determination of the subtype of breech), other nonvertex presentations, prolapsed umbilical cord, and multigestation delivery. Shoulder dystocia, though certainly an abnormal presentation, is easily differentiated by its occurrence after the delivery of a vertex head. One must also be vigilant for the potential aforementioned complications associated with breech delivery—a nuchal arm (fetal arm entrapped posterior to the neck) and a prolapsed, entrapped cord.

When the sterile glove examination is performed, the physician may feel either the buttocks (including the sacral bone, ischial tuberocities, and anus—the latter two occurring in a horizontal line with respect to each other) or one of the extended fetal legs. Insertion of a finger into the fetal anus should reveal the reflexive sphincter tone. There may also be meconium on withdrawal of the finger. Still, most ED physicians lack practical experience in identifying fetal presentation.

Ultrasound is extremely helpful in confirming fetal lie if it is available on an emergency basis. To date, no studies have evaluated the diagnostic ability of bedside ultrasound performed by emergency medical physicians in the setting of emergency delivery. Although information obtained from this modality is helpful, it does not directly alter the basic management principles of emergency delivery of a breech fetus; instead, it clues the physician to a potentially difficult delivery and underscores the need for urgent obstetric assistance.

After assessment of the ABCs (airway, breathing, and circulation) of the mother, evaluation of fetal heart tones (FHTs), and a brief focused history, the physician should arrange for immediate obstetric/gynecologic and NICU assistance. Even though many breech presentations will be delivered with minimal complications, a significant proportion will not. Therefore, if at all possible, transfer to a facility with in-house obstetrics is indicated. If delivery is unavoidable, adequate nursing assistance will be needed. Frequent serial FHT measurements can be used to document fetal health, but ED management in the absence of obstetric/gynecologic assistance will not change based on these heart rates.

Although a few ancillary maneuvers may be called for during a breech delivery, the most important one is patience. It is generally agreed that the physician need only provide support to the mother until the umbilicus is at the introitus for two reasons. First, the cervix needs to have sufficient time to dilate to prevent entrapment of the aftercoming head. Second, traction on the fetal body will cause it to descend in the pelvis and remove the potential stabilizing effect of the contracted uterus on the fetal head. Without this effect, the head is likely to move from normal, stable flexion to extension. Hyperextension of the neck during passage can cause catastrophic cervical spine injury.

Maternal expulsive efforts are the primary force required to deliver the fetus. If it becomes clinically necessary, an episiotomy may be performed to provide additional working room and easier passage of the fetus. In addition, throughout any of the following maneuvers, gentle downward traction should be applied. Once accessible, the bony pelvis should be the landmark used to successfully grip and manipulate the fetus. A warm, wet towel over the fetus can help prevent slippage associated with vernix.

Although they often pass spontaneously, the legs may need assistance to be freed in a frank breech presentation. Once the buttocks have passed through the introitus, the provider frees a given leg by placing two fingers on medial aspect of the thigh and pushes laterally while holding the fetal body stable. This external rotation brings the knee through the introitus and frees the leg. This maneuver is then repeated on the other leg (Fig. 122.4).

No more than gentle downward traction should be applied until the fetal scapulae are visible. At this point, rotation of the fetal torso 90 degrees in one direction should elicit delivery of a shoulder, followed by 180-degree rotation in the other direction for the remaining shoulder (clockwise for the left and counterclockwise for the right) (Fig. 122.5). The goal is
to turn the fetus “into” the shoulder that is attempting to be freed. If this maneuver does not free the shoulder, a nuchal arm should be suspected. The physician should attempt to manually splint and sweep the flexed arm over the thorax (in a manner similar to posterior shoulder delivery for shoulder dystocia) to enable its passage. Upper extremity and clavicle fractures are a common complication.

The Mauriceau maneuver (Fig. 122.6) is used if the fetal head fails to pass easily. The physician slips the index and middle fingers under the anterior surface of the fetus and places them against the fetal maxilla. The fetal torso therefore rests on the physician’s forearm with the legs straddling down. The other hand is then inserted over the fetal back to grasp the shoulders and provide downward traction in concert with traction on the maxilla, not the mandible, to keep the fetal head in flexion during its removal. The physician should kneel on one knee while performing this maneuver to be at the level of the maternal pelvis and prevent the tendency to lift the fetus (and extend the neck) while extracting. Ancillary staff may provide suprapubic pressure to assist in this maneuver, which should be performed in tandem with maternal expulsive efforts.

Once delivered, the neonate should be assessed and resuscitated in the usual fashion. Treatment of the mother should continue as usual until passage of the placenta and assessment for hemorrhage or other postpartum complications.

If at any point an entangled umbilical cord should become apparent, manual decompression should be performed. If it cannot be manually reduced immediately, all maternal efforts to push should be stopped, and emergency cesarean section is required. Other temporizing measures include placing the mother in the knee-chest position, filling the bladder with saline, or tocolysis—ideally these measures should be decided with obstetric consultation.

Face, brow, and transverse presentations are simple to manage from an emergency medicine perspective. Face and brow presentations may spontaneously evolve to a favorable situation, thereby giving rise to the obstetric adage “if a face is progressing, leave it alone.” Any facial or brow presentation that does not progress and every transverse lie require surgical intervention. There are no additional ED maneuvers for these presentations, only for their potential complications such as prolapsed cord or hemorrhage.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Obstetric consultation should be obtained on an emergency basis to assist in the delivery and postpartum care of the mother, as well as pediatric or neonatal services for the newborn. All patients who deliver in the ED should be admitted to an obstetric floor after delivery or stabilization of the acute complication.

**CORD-RELATED Complications**

**EPIDEMIOLOGY**

Higher rates of prolapse and entanglement are associated with abnormalities in fetal presentation, such as abnormal lie, breech orientation, and compound presentation, with prematurity, and with multiple gestations. A nuchal cord is extremely common, with at least one loop appearing in upward of 30% of pregnancies. This finding alone rarely results in fetal morbidity and should perhaps be considered a normal variant.

**PATHOPHYSIOLOGY**

Umbilical cord complications can occur in any delivery. Because of the compact environment, the fetal limbs are closely approximated to the body and are rarely the site of entanglement. Instead, loops of cord are more commonly found around the neck or fetal torso. Compression most often
Fig. 122.6 Cephalic flexion is maintained by pressure (heavy arrow) on the fetal maxilla (not the mandible). Frequently, delivery of the head is easily accomplished with continued expulsive force from above and gentle downward traction. (From Gabbe SG, Niebyl JR, Simpson JL, et al. Obstetrics—normal and problem pregnancies. 5th ed. Philadelphia: Churchill Livingstone; 2007.)

Fig. 122.5 When the scapulae appear under the symphysis, the operator reaches over the left shoulder, sweeps the arm across the chest (A), and delivers the arm (B). Gentle rotation of the shoulder girdle facilitates delivery of the right arm (C). (From Gabbe SG, Niebyl JR, Simpson JL, et al. Obstetrics—normal and problem pregnancies. 5th ed. Philadelphia: Churchill Livingstone; 2007.)

Umbilical cord prolapse is a fairly straightforward diagnosis that is made by identifying the cord on passage through the introitus or by palpation during vaginal examination. Given the unreliable presence of continuous tococardiographic monitoring in the ED, monitoring of the fetal heart rate cannot be the main modality used to help diagnose occult cord compression. Nuchal or torso loops are common, and several loops may be identified. Rarely, knots, kinks, or torsion of the cord occurs as the cord passes through the cervix or, rarely, from tension applied around an entangled fetal part. The most important factor in these situations is patency of the umbilical vessels with sufficient blood flow. If a cord is tightly entrapped or impacted on a structure, blood flow will be inadequate and fetal hypoxia will result. Functionally, the only way to prevent fetal hypoxia in this situation is to restore umbilical blood flow either by manually decompressing the cord or by completing delivery so that the fetus is capable of oxygenating independently.
may occur. Diagnosis of a fetus with abnormal presentation raises the likelihood of a cord emergency. No ancillary radiographic or laboratory tests can be used to diagnose a prolapsed or entrapped cord.

**TREATMENT**

As with any patient in labor, the ABCs, FHTs, and a brief focused history are the first priority. Early obstetric and neonatal help should be called once either emergency delivery or a cord-related complication is recognized. Sufficient ancillary staff to resuscitate two patients should be available, and a type and crossmatch should be ordered for both potential hemorrhage and Rh antigen determination.

As soon as cord prolapse is recognized, the treatment of choice is emergency cesarean section. Manual decompression of the umbilical cord from the fetal presenting part must be maintained until cesarean section is performed. If accomplished in less than 10 minutes, infant mortality from prolapse drops significantly. Compression usually occurs at the level of the cervix because this is the point of smallest diameter in the birth canal (especially when the presentation is nonvertex). When prolapse is recognized, all maternal pushing should cease. The clinician must provide continuous manual separation of the presenting part from the cord to maintain patent flow until an emergency cesarean section is performed. Other techniques to assist in removing some pressure from the cord are to place the mother in either the Trendelenburg or knee-chest position while continuing to hold manual decompression.

In the rare instance in which obstetric surgical assistance is not going to be available on a timely basis, the provider may need to manually reduce the cord into the uterus and rapidly deliver the fetus vaginally. Reduction of the cord into the uterus, called funic reduction, should be done only when consultation with an obstetrician reveals that no other viable option is available to quickly treat the prolapse.

In the case of nuchal or body loops, it should be remembered that a loose loop of cord will probably still have good perfusion. It has been repeatedly demonstrated that a nuchal cord alone does not have a significant impact on fetal outcomes. Therefore, in the absence of arrest of labor or identifiable cord entrapment, the cord should simply be reduced from the fetal neck and labor allowed to proceed as usual. However, excessive manipulation of the cord should be avoided to prevent vasospasm. Once the fetal mouth and nares are suctioned and spontaneous respirations are initiated, the cord may be clamped and separated from the neonate in the usual fashion.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Obstetric consultation should be obtained on an emergency basis to assist in the delivery and postpartum care of the mother, as well as pediatric or neonatal services for the newborn. All patients who deliver in the ED should be admitted to an obstetric floor after delivery or stabilization of the acute complication. Actively prolapsed cords need to be manually decompressed and the mother taken to the operating room for delivery by cesarean section on an emergency basis.

**SHOULDER DYSTOCIA**

**EPIDEMIOLOGY**

Shoulder dystocia is recorded to occur in anywhere from 0.2% to 3% of all births—the variance being caused by discordant definitions of this condition. Spong et al. proposed criteria that include greater than a 60-second delay between delivery of the fetal head and delivery of the body or the use of ancillary delivery maneuvers, but this was found to prospectively identify only 72% of cases of shoulder dystocia.

Many risks for shoulder dystocia have been proposed, including (but not limited to) fetal macrosomia, maternal diabetes, maternal obesity, and previous history of dystocia. However, most studies that have posited these risk factors for dystocia are retrospective and are not borne out prospectively. The most consistent risk factor is fetal macrosomia—based on actual, not estimated weight. Still, even for neonates weighing more than 4000 g at delivery, shoulder dystocia will complicate only 3.3% of deliveries.

Although its occurrence can be terrifying, death from dystocia is relatively rare. One study showed the approximate incidence of fatal shoulder dystocia to be 0.025 per 1000 deliveries. The most common injury associated with shoulder dystocia is brachial plexus palsy, which has been reported in up to 20% of deliveries involving shoulder dystocia. Thankfully, the large majority of these palsies are transient.

**PATHOPHYSIOLOGY**

In shoulder dystocia, the fetal shoulders fail to clear the pelvis properly. The fetus assumes a position that places the shoulders in an anteroposterior plane between the pubis and sacrum, whereas in a normal delivery they are slightly oblique from this orientation. This abnormal position forces the fetus to pass through a narrower pelvic diameter, which results...
in shoulder impaction. Most of the time the impaction occurs when the anterior shoulder fails to clear the pubis. Maneuvers that augment these impactions are the basis of treatment.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Shoulder dystocia is caused by arrest of labor after passage of the fetal head. It classically results in the “turtle sign,” in which the fetal head retracts against the perineum after it is delivered because of shoulder impaction on the pelvis. Because most causes of arrest of labor occur before passage of the head, the only other significant clinical entity to consider is uterine rupture. In this instance, failure of uterine integrity leads to compromised fetal expulsive force and similar retraction of the fetal head. This complication is discussed in the earlier section of this chapter on causes of postpartum hemorrhage.

The diagnosis of dystocia is typically confirmed when application of gentle downward traction does not lead to progression of labor. The head is typically facing 3 or 9 o’clock with respect to the mother. The majority of cases of dystocia are described as being related to anterior shoulder impaction. Posterior or bilateral shoulder dystocia can also occur and should be suspected if the initial maneuvers aimed at clearing the anterior shoulder fail to produce fetal passage. This degree of impaction is quite complicated and will probably require obstetric expertise to alleviate.

Shoulder dystocia is a purely clinical diagnosis. No laboratory or radiologic testing is needed or helpful in its diagnosis.

**TREATMENT**

The most important issue in treating shoulder dystocia is to be prepared; providers must quickly recognize its clinical features and be knowledgeable about treatment techniques. Panicked forceful traction on the fetal head and neck will not disimpact a dystocia and may lead to fetal injury, which may include fetal clavicular or humeral fracture, brachial plexus injury, or worst of all, fetal hypoxia with brain damage or death.

Shoulder dystocia must be suspected if passage of the fetal body is delayed after delivery of the head. If it has not already been done, an obstetrician and NICU or pediatrician staff member should be called for assistance immediately. The mother should be monitored appropriately, and if available, a FHT monitor should be applied. If the latter is not possible, tococardiographic measurements should be obtained and trended.

If the anterior shoulder does not deliver spontaneously, the provider may grasp both fetal parietal eminences and provide downward shifting motion traction to “slip” the shoulder under the pubis. A rotary, fulcrum, or bending motion that brings one fetal ear closer to the ipsilateral shoulder should be avoided to prevent brachial plexus injury (Fig. 122.8).

The delivering physician should exert mild downward traction on the fetal head while keeping the cervical spine in line. This maneuver prevents use of the head as a fulcrum to “pry” the shoulder free, which could lead to stretching of the fetal neck and brachial plexus. If this does not result in fetal progression, the McRoberts maneuver should be performed next. Ancillary staff should provide suprapubic pressure concurrently. The McRoberts maneuver (Fig. 122.9) is performed by tightly flexing the maternal hips or knees to “pull” the pubis back over the anterior fetal shoulder, ideally inducing its passage. This maneuver is favored first by most clinicians because of its simplicity and effectiveness—retrospective studies, however, indicate it works approximately 40% of the time. These studies have shown that if this maneuver is combined with suprapubic pressure, the success rate climbs to between 54% and 59%.

Suprapubic pressure (Fig. 122.10) is intended to aim a force directly over the site of the impacted shoulder and assist it in sliding beneath the pubis. Fundal pressure has not been shown to be effective in disimpacting a shoulder and should not be used. If the mother is clinically stable and there is a stable surface on which to perform it, the “all-fours” or “Gaskin” position may be attempted. The reversal of gravitational force combined with altered pelvic dimensions may result in disimpaction—50% of cases in one series were managed by this technique alone. The aforementioned maneuvers may be repeated in this position.

If these techniques are not successful, the physician should attempt a Woods screw or Rubin maneuver. In the Woods screw maneuver the physician palpates the posterior shoulder and exerts a force on its anterior side to effect a rotation. This brings the posterior shoulder around to the anterior side, which both frees the anterior shoulder and aligns both shoulders in the ideal oblique pelvic plane. The Rubin maneuver (Fig. 122.11) is another rotational technique that is the reverse of the Woods screw maneuver: pressure is applied from the posterior side of whichever shoulder is reachable until fetal axial rotation occurs. Some inward pressure on the fetal head (into the vagina) may be required to disimpact a wedged shoulder before these techniques are used. The decision to perform either maneuver should be based on accessibility of the fetus and clinical response to their implementation.
The least invasive maneuver to disimpact the shoulders is the McRoberts maneuver. Sharp ventral flexion of the maternal hips results in ventral rotation of the maternal pelvis and an increase in the useful size of the outlet. (From Gabbe SG, Niebyl JR, Simpson JL, et al. Obstetrics—normal and problem pregnancies. 5th ed. Philadelphia: Churchill Livingstone; 2007.)

If these maneuvers fail, delivery of the posterior arm should be attempted. This should be the last intrapelvic maneuver attempted given its high association with fetal injury. Delivery of the posterior shoulder aims to reduce the bisacromial diameter (shoulder width) of the fetus, thereby returning the fetus to a dimension that can pass through the pelvis. This maneuver is technically difficult, and clavicular and humeral fractures with associated nerve damage may occur. The physician locates the posterior arm and first flexes the forearm with pressure applied into the acromioclavicular fossa. The flexed arm is then adducted over the chest of the fetus and out of the maternal pelvis (Fig. 122.12). If labor does not proceed with this maneuver alone, it may be combined with one of the aforementioned rotary techniques.

If access to the intrapelvic fetal body is suboptimal, an episiotomy is indicated. However, it is important to note that episiotomy is no longer routinely recommended during delivery. Management by episiotomy or proctoepisiotomy has been associated with a nearly sevenfold increase in the rate of severe perineal trauma without the benefit of reducing the occurrence of neonatal depression or brachial plexus palsy. Because of these findings, episiotomy is now recommended only on a clinical as-needed basis to perform maneuvers required to disimpact the fetal shoulders. Episiotomy alone will not alleviate the dystocia because it does nothing to correct the underlying impaction of the shoulder on the pelvis—it merely provides improved access to the fetal body to perform manipulations required to complete delivery. To perform an episiotomy, the vaginal fourchette and perineum are first anesthetized with 1% to 2% lidocaine. The physician’s fingers are used to both expose the area to be incised and provide a physical block between the scissors and the
Fig. 122.12 The operator inserts a hand and sweeps the posterior arm across the chest and over the perineum. Care should be taken to distribute the pressure evenly across the humerus to avoid unnecessary fracture. (From Gabbe SG, Niebyl JR, Simpson JL, et al. Obstetrics—normal and problem pregnancies. 5th ed. Philadelphia: Churchill Livingstone; 2007.)

delivering fetus. The scissors are then used to incise through about one half of the perineum. Care must be taken to try to avoid extending into the anal sphincter or, worse yet, into the anal mucosa and cause third- or fourth-degree lacerations, respectively.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Obstetric consultation should be obtained on an emergency basis to assist in the delivery and postpartum care of the mother, as well as pediatric or neonatal services for the newborn. If evidence of fetal distress develops or if routine maneuvers fail to lead to progression of labor, emergency delivery by cesarean section may be necessary.

PREMATURE RUPTURE OF MEMBRANES AND PRETERM PREMATURE RUPTURE OF MEMBRANES

EPIDEMIOLOGY

Rupture of fetal membranes occurring without evidence of labor is called PROM. It occurs infrequently—less than 5% of pregnancies are affected. If this event takes place before 37 weeks' gestation, it is called PPROM. Factors that have been associated with PROM include infections, maternal smoking, placental abnormalities such as abruption or previa, malnutrition, and connective tissue disorders.

PATHOPHYSIOLOGY

The chorion and amnion make up the commonly labeled “membranes” that surround the growing fetus, with the tougher and thicker chorion surrounding the thinner and more elastic amnion. As pregnancy progresses, the structural integrity of these membranes degrades. This breakdown, combined with a dilating cervix to act as a focal stress point, is thought to allow timely, spontaneous rupture in a normal delivery.

Amniotic fluid contents have certain biochemical differences from vaginal fluid, and these differences are the basis of some common tests that allow accurate diagnosis of PROM: a higher pH (higher in amniotic than in vaginal fluid) and the tendency of amniotic fluid to microscopically crystallize or “fern” when allowed to air-dry on a glass slide.
DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The differential diagnosis for fluid leakage includes bleeding, infection, and urinary incontinence. A good history, combined with sterile speculum examination possibly supplemented by Nitrazine pH testing, will often differentiate these causes.

The most common complaint in patients with PROM and PPROM is passage of fluid from the vagina. It may be very small in quantity or comparable with the volume noted at the onset of normal labor. There is often continuous seeping of fluid with visible pooling in the posterior vaginal vault, and the physician may notice leakage of clear fluid from the still-closed cervix. This leakage may be exacerbated by fundal pressure or coughing.

The history will often reveal a lack of associated contractions, although the presence of Braxton-Hicks contractions may complicate the diagnosis; differentiation is best left to the obstetrician with access to full maternal-fetal monitoring. However, sterile speculum examination in the ED should allow adequate visualization of the cervix to determine whether it is dilated.

The most significant variant is premature rupture with chorioamnionitis. Symptoms that suggest this infection are fever, uterine tenderness, maternal or fetal tachycardia, malodorous vaginal discharge, or elevated maternal white blood cell count. However, none are sufficiently sensitive or specific alone.

MANAGEMENT AND DISPOSITION

As with every third trimester patient encounter, assessment and stabilization of maternal ABCs and fetal FHTs are the initial priorities. If the patient complains of passage of fluid, sterile speculum examination is performed to determine whether any cervical dilation has occurred. If active crowning is observed, ED delivery should be anticipated. If signs of active labor are present but no presenting part is visible, digital examination is indicated to further assess dilation, station, and effacement. If fluid is noted on examination without associated signs of labor, digital examination is contraindicated and a work-up for PROM or PPROM can begin.

Beyond recognition of PROM and PPROM, the most important intervention is to abstain from a digital vaginal examination. The risk for chorioamnionitis after premature membrane rupture appears to be directly related to the number of examinations performed. Recent data suggest that there is no increase in infectious complications if the number of examinations is less than two. Nevertheless, only a sterile speculum examination should be performed in the ED.

Nitrazine testing of vaginal fluid may be performed because of its speed and simplicity. This information may be helpful for the consulting obstetrician but will probably not change management in the ED. Most EDs are equipped with Nitrazine, typically for opthalmologic evaluation, and performance and interpretation of this test can take place at the point of care. The vagina is typically an acidic environment, so a pH higher than 6.5 is consistent with ruptured membranes. Published sensitivities for this test range from 77% to 92%, with false results most commonly being caused by inadequate samples or the presence of blood or bacterial infection of the vagina. Many EDs do not have a microscope easily available, and thus testing for ferning of the suspect fluid may be impractical.

Particular attention should be focused on evaluating for chorioamnionitis. If maternal fever or unexplained tachycardia is present, the clinical examination should focus on other signs or symptoms of chorioamnionitis. For fetuses younger than 34 weeks and potentially as late as 37 weeks, prophylactic antibiotic administration for PPROM has significantly improved outcomes. For patients after 37 weeks, who by definition have PROM, the question of antibiotics is less clear. Unless clear evidence of infection or sepsis is present, consultation with the obstetrician before administering antibiotics is prudent.

Tocolytics are often used to prevent progression of labor along with coincident steroid administration to hasten fetal lung maturity in premature infants. However, unless the time to transfer of care is anticipated to be long, these agents should probably not be administered in the ED—and certainly not without obstetric consultation.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Obstetric consultation should be obtained on an emergency basis to assist in the care of a patient with suspected rupture of membranes, and in general, all these patients should be admitted or transferred to obstetric care for further management.

MULTIPLE GESTATIONS

EPIDEMIOLOGY

Since the advent of and mainstream access to in vitro fertilization treatments, the incidence of multiple-gestation pregnancies has risen greatly. However, these same patients are less likely to be in the pool of patients seen in labor in the ED because of the intensive prenatal care associated with fertility treatments. Patients who have twin or greater gestation by spontaneous means are also very likely to know of their status and have heightened prenatal care. Multigestation pregnancies have an inherently higher risk profile that increases with the number of fetuses, with the main factor being the higher tendency toward lower birth weight.

PATHOPHYSIOLOGY

During gestation the fetus is surrounded by two separate membranes—the outer chorion and the inner amnion. This anatomic arrangement can be altered in the case of multiple gestations (twins, the most common multiple gestation, will serve as the reference point here) (Fig. 122.13).

In dizygotic twins (DZ), two separate ova, introduced by either multiple ovulation or in vitro fertilization, are subsequently fertilized by two separate sperm. This results in twins that are as genetically different as siblings born at separate

Dichorionic diamniotic (fused placenta)

Dichorionic diamniotic (separate placenta)

times. All these twins have a separate chorion and amnion in utero, although their placentas may fuse into one if they implant in close proximity.

In the case of monozygotic twins (MZ), a single zygote splits shortly after fertilization. The timing of this split determines whether there will be two separate chorions and amnions, a shared chorion with two distinct amnions, or a shared chorion and amnion. The risk associated with the pregnancy progressively increases through the aforementioned situations, with dichorionic, diamniotic MZ twins having the same risk profile as a DZ twin pregnancy. In addition to the risks associated with any multigestation pregnancy, monochorionic, monoamniotic twins are susceptible to other unique complications stemming from their shared anatomy. This can range from vascular anastomoses leading to twin-twin transfusion syndrome through the creation of conjoined, or Siamese, twins.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The vast majority of twin pregnancies are discovered during prenatal ultrasound. Higher suspicion for a multigestation pregnancy in the ED should occur with patients who have not had prenatal care, if a uterus feels larger than anticipated for dates, or if contractions seem to continue after delivery of the first fetus. The most clinically useful tool is bedside ultrasound, which should easily distinguish a multigestational pregnancy.

Twin A will be in a vertex position about 80% of the time, with twin B being in vertex only half as often. Therefore, one must not only anticipate the high likelihood of prematurity associated with multiple gestations but must also be prepared for the potential for a nonvertex delivery for twin B.

TREATMENT

As with every gravid patient, evaluation of the ABCs and FHTs and a brief focused history are the first priorities. Obstetric and NICU assistance should be requested immediately, particularly given the universally increased morbidity and mortality associated with multiple gestations.

In the absence of complications, the delivery itself is handled the same as a singleton delivery—just repeated per each fetus. If a multigestation pregnancy is identified, arrangements for enough resources to handle the mother and each of the new patients need to be made early. After delivery of the first child, there is a variable period before active labor of the subsequent child. Maternal monitoring and frequent FHT evaluation should be performed during this time.

If twin A is nonvertex, every effort should be made to delay labor until a cesarean section can be performed. If twin A is vertex and B is not, attempted vaginal delivery is recommended if the estimated fetal birth weight (EFW) is greater than 2000 g. However, EFW measurements are not routinely performed in the ED, nor are continuous monitoring modalities or providers experienced in twin deliveries available. Therefore, the clinical status of the second twin and the availability of obstetric assistance should be used to decide the best course of action for twin B. The delay between delivery of twin A and twin B may be fortuitous and provide the needed time for obstetric assistance to arrive and assume care. If no help is available and crowning is occurring, the nonvertex twin B should be handled as any other nonvertex delivery.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Obstetric consultation should be obtained on an emergency basis to assist in the delivery and postpartum care of the mother, as well as pediatric or neonatal services for the newborn or newborns. All patients who deliver in the ED should be admitted to an obstetric floor after delivery or stabilization of the acute complication. If twins are known and twin A is nonvertex, delivery by cesarean section is indicated.
REFERENCES

Additional, there is a high frequency of late maternal morbidity from a variety of causes; up to 87% of women note problems in the first 6 weeks postpartum, and as many as 76% of these patients continue to have these problems for as long as 18 months following delivery.

**PATHOPHYSIOLOGY: THE PUERPERIUM**

Originally, the puerperium was defined as the period of confinement during and just after birth; it is now generally accepted to mean the 6 weeks after delivery. The puerperium has also been referred to as “the fourth trimester.” This period is marked by multiple physiologic changes (Table 123.1) as the woman returns to the prepregnant state, including healing physically from any trauma during delivery, and adjusts to the many physiologic and psychologic demands involved in caring for a newborn. Just as in pregnancy, when there are so many physiologic changes, the potential exists for the normal healing process to go awry and emergencies to occur.

Certain significant changes in the physiology of the coagulation system during pregnancy persist past delivery and into the puerperium, including major changes in the coagulation and fibrinolytic system, as well as a reduction in venous blood flow in the deep venous system. Combined, these alterations increase the thrombotic potential in near-term and immediate postpartum patients.

A pregnant patient around term and immediately postpartum has significant increases in factors I, V, VII, IX, X, and XII; von Willebrand factor antigen; and ristocetin cofactor activity. The endogenous anticoagulants protein C and antithrombin remain unchanged throughout pregnancy, but levels of protein S are reduced. Fibrinolytic activity is impaired during pregnancy as a result of placentally derived plasminogen activator inhibitor type II and pregnancy-induced increases (approximately threefold) in endothelial and hepatic-derived inhibitor of plasminogen activator type I. These changes rapidly return to normal following delivery.

During normal pregnancy there is a significant reduction in blood flow to the deep venous system, as well as an increase in diameter of the major leg veins. These changes do not occur evenly in both legs. Studies of patients in the puerperium have reported greater diameter and slower blood flow in the left common femoral vein than in the right. These differences are manifested clinically; in nonpregnant patients, the left leg was affected in 55% of cases of DVT, whereas in pregnancy the
rate was 85%. The mode of delivery also affects the deep venous system. Women who delivered by cesarean section had a lower mean velocity of blood flow in the common femoral vein during the puerperium than did those who had delivered vaginally. These changes in flow velocity and diameter take approximately 6 weeks to return to baseline. Another significant clinical difference observed in pregnant and immediate postpartum patients is that the majority of DVT events seen during this time occur in the iliofemoral segments rather than in the calf veins and are therefore more likely to result in PE.

Additional underlying risk factors that increase the likelihood for thrombotic complications are age older than 35 years, delivery by cesarean section, weight greater than 175 lb, and a family or personal history of thrombosis and thrombophilia (protein C or S deficiency, factor V Leiden).

### PRESENTING SIGNS AND SYMPTOMS

The most common complaints in the postpartum period are fatigue (56%), breast problems (20%), backache (20%), depression (17%), hemorrhoids (15%), and headache (15%).

The signs and symptoms of metritis are fever, uterine tenderness, abdominal pain, and either purulent lochia or a positive culture of endometrial fluid or tissue usually between the second and seventh days postpartum. Fever (>38°C [100.4°F]) is the most important criterion for the diagnosis of metritis. Lochia may be foul smelling or have no odor.

Peritonitis is manifested as severe abdominal pain but may be misdiagnosed because abdominal rigidity, guarding, or rebound tenderness are often not present on physical examination as a result of laxity of the rectus abdominis muscles. Commonly, an adynamic ileus is the first sign.

Symptoms of toxic shock syndrome (TSS) include fever with a temperature of 39°C (102.2°F) or higher; erythematous diffuse rash; headache, photophobia, myalgias, and altered sensorium; gastrointestinal complaints, including nausea, vomiting, and watery diarrhea; and rapid progression to renal failure, hepatic failure, disseminated intravascular coagulation, and circulatory collapse.

Clinical signs and symptoms associated with cardiopulmonary complications may include fatigue, dyspnea, cough, orthopnea, hemoptysis, chest pain, palpitations, abdominal pain, tachycardia, elevated blood pressure, pulmonary rales, third heart sound, mitral regurgitant murmur, and peripheral edema.

Symptoms of postpartum mood disturbance include mild depression, irritability, confusion, mood instability, anxiety, headache, fatigue, and forgetfulness. Usually, the postpartum blues appear in the first 2 weeks after delivery and last from

a few hours to a few days. More severe symptoms may include delusions, hallucinations, rapid mood swings, sleep disturbances, and obsessive thoughts about the baby.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

### INFECTIONS

Puerperal fever is defined as a temperature of 38° C (100.4° F) or higher that occurs on any 2 of the first 10 days postpartum, exclusive of the first 24 hours; the temperature should be taken orally by a standard technique at least four times daily. The usual cause is a genital tract infection, which can lead to significant morbidity and mortality.

In a small proportion of women, postpartum fever will develop as a result of breast engorgement, but the fever rarely exceeds 39° C (102.2° F) in the first few postpartum days and usually lasts less than 24 hours.

The most common infection in the postpartum period is a genital tract infection, but other sources must be eliminated, especially urinary tract infection and pneumonia. The puerperal bladder is prone to urine retention, especially after instrumental delivery and epidural analgesia; in addition, dilatation of the ureters and renal pelvis makes them potential sites of infection.

Mild hyperventilation after delivery as a result of pain or limited ambulation, or both, predisposes some women to pneumonia. Additionally, minor elevations in temperature are occasionally caused by thrombosis of the superficial or deep veins of the lower extremities (Box 123.1).\(^1,^6\)

## GENITOURINARY

**Metritis and Pelvic Infections**

In the past, uterine infections had different names based on the assumed location of the infection; however, the accepted terminology is now metritis or metritis with cellulitis. In 6% to 18% of cesarean deliveries, there is a 6% to 18% incidence of metritis versus 0.9% to 3.9% with vaginal deliveries.\(^7,^8\) Other recognized risk factors for the development of metritis are chorioamnionitis, anal sphincter laceration, prolonged rupture of membranes, and weight on admission of more than 200 lb.

Rates of metritis are lower now than in the past 2 decades because of the routine use of prophylactic antibiotics for cesarean deliveries.\(^6,^7\)

Leukocytosis is often present but the white blood count is frequently elevated during the first 2 weeks postpartum. Chills may indicate bacteremia, which occurs in 10% to 20% of women with pelvic infection. Blood for culture is best obtained during the peak temperature elevations and chills that are associated with bacteremia.\(^9\) Complications of pelvic infections can be quite severe. If a patient with metritis does not respond to antibiotics after 48 to 72 hours, suspicion for complications should be high.

Wound infections are the most common cause of antimicrobial failure in women treated for metritis and are usually associated with fever around the fourth postoperative day in patients who deliver by cesarean section. Wound dehiscence, or separation of the fascial layer, is a complication of incisional infections and is associated with fascial infection and tissue necrosis.

One of the most severe complications of a pelvic infection is necrotizing fasciitis. It has a devastatingly high mortality of approximately 50%, even with appropriate treatment, and may be a complication of a cesarean incision, episiotomy, or perineal laceration. Risk factors for necrotizing fasciitis are diabetes, obesity, and hypertension.

Other complications include pelvic phlegmon, which is cellulitis that has extended to the broad ligament. These infections can extend into any blood collections that develop after a cesarean delivery, such as under the bladder flap, and cause an infected hematoma. If left untreated, a phlegmon can suppurate into an abscess. Pelvic abscesses can develop in the broad ligament, ovaries, rectovaginal septum, or psoas muscle.

Infections can extend into the veins and cause septic pelvic thrombosis, which usually involves one or both ovarian venous plexuses and occurs more predominantly on the right because of the slightly longer vein on the right and dextrotorsion of the puerperal enlarged uterus. In 25% of patients, these clots extend into the inferior vena cava and occasionally into the renal veins.

**Toxic Shock Syndrome**

TSS is a rare but worrisome postpartum infection with a mortality of 10% to 15%. Group A streptococci and *Staphylococcus aureus* are the predominant causes of TSS. These bacteria colonize the mucosa of the vaginal tract and infect the postpartum uterus, cervix, and vagina, all of which are susceptible as a result of the trauma that accompanies delivery. Most cases of TSS occur in the first 8 weeks postpartum, but TSS can be seen up to week 10.

**Perineal Pain**

Although some discomfort is to be expected after delivery because of disruption and distention of the soft tissues of the birth canal, painful perineal tissue is a significant issue for many women. In fact, perineal pain was noted by 42% of recently delivered women to be a significant problem in the first 2 weeks following delivery, and as might be expected, the percentage was higher in patients with assisted vaginal deliveries (84%). By 8 weeks postpartum the percentage was down to 22% and by 12 weeks down to approximately 7%.\(^5\)

Careful examination is required for these patients, especially those with persistent and significant discomfort, to look
for evidence of hematoma formation, abscess, or genital tract infections such as cellulitis and necrotizing fasciitis.

**Urinary Tract Dysfunction**

The puerperal bladder is predisposed to some urinary retention, as well as urinary tract infections, especially in patients who had instrumentation or prolonged labor in delivery, as well as epidural or spinal analgesia. In the immediate postpartum period, the bladder has increased capacity and relative insensitivity to increased intravesical pressure. The ureteral and renal pelvic dilation seen in late pregnancy takes approximately 2 to 3 months to resolve. These factors, combined with stasis of urine, create an excellent environment for development of a urinary tract infection. Any patient with a complaint of urinary retention should have catheterized urinalysis performed and urine sent to the laboratory for culture to rule out urinary tract infection.

**LACTATION AND BREAST DYSFUNCTION**

Milk leakage, breast engorgement, and breast pain peak at 3 to 5 days postpartum.

A milk duct can be clogged by inspissated secretions or milk forming a galactocele. It may form a fluctuant mass and resultant pain.

**Mastitis**

In women who breastfeed, mastitis is a common problem that usually peaks between the second and sixth postpartum weeks. Most often the mastitis is unilateral and is caused by infant oral bacterial flora and relative obstruction of a milk duct. The most commonly isolated organism is *S. aureus*.

The affected breast appears hard and reddened, and the patient complains of severe pain. An abscess develops in 10% of women with mastitis. Patients with breast abscesses may have constitutional symptoms of fevers, chills, or rigor along with fluctuance of the area. Ultrasonography can be useful in detecting an abscess.

**GASTROINTESTINAL**

Abdominal pain is a common complaint in the puerperium. In fact, one questionnaire given to women 48 hours after vaginal delivery noted that 50% of primiparous and 86% of multiparous women complained of lower abdominal pain.10

Abdominal pain can be a difficult complaint to evaluate in postpartum patients and requires a higher level of suspicion for a surgical emergency or infectious or thrombotic complications. Because patients expect to experience a certain amount of pain and discomfort after delivery, they often come late to the ED with these symptoms. During the preliminary ED evaluation it may be difficult for the emergency physician to adequately assess these patients without imaging, and the proper diagnosis may be further delayed.

**Appendicitis**

In puerperal patients with appendicitis, peritoneal tenderness may not be present as a result of laxity of the rectus abdominis muscles following pregnancy. The uterus is still enlarged for much of the puerperium, and because the appendix is displaced upward toward the right upper quadrant and the abdominal wall is lifted away from the inflamed appendix, clinically apparent signs of peritoneal irritation are minimized. The psoas, obturator, and Rovsing signs are not predictive of appendicitis in pregnant and postpartum women. Other tests have been suggested such as the Bryan sign (pain elicited by movement of the enlarged uterus to the right) for appendicitis and the Alder test (maintaining constant pressure at the area of maximum tenderness while the patient rolls from a supine position to the left side) to differentiate pain of intrauterine origin (which diminishes as the uterus falls away with the maneuver) from pain of extrauterine origin. The sensitivity and specificity of these tests are unknown.

The incidence of appendicitis is not increased during the puerperium, although outcome is poorer because of delayed diagnosis. The incidence of certain pathologies such as obstruction, ileus, acute cholecystitis and peritonitis, and Fitz-Hugh-Curtis syndrome (often misdiagnosed as acute cholecystitis) is increased during this period. Postpartum ileus is usually associated with cesarean section; other obstructions may occur more frequently as a result of compression of the enlarged uterus. Peritonitis is often a sequela of latent or asymptomatic infection. Ovarian cysts and torsion need to be ruled out in the differential diagnosis, as well as complications of metritis and urinary tract infections.

Evaluation tools include a careful pelvic examination with appropriate cultures to rule out infection of the genital tract, a catheterized urine specimen to avoid contamination with lochia for urinalysis and culture, and standardized laboratory values such as electrolytes, liver function tests, serum amylase, and a complete blood count. In puerperal patients with appendicitis, urinalysis may show a sterile pyuria of more than five white blood cells per high-power field, and 15% to 30% of these patients have hematuria as a result of the proximity of the inflamed appendix to the ureter. The white blood cell count is difficult to interpret in puerperal patients because of the leukocytosis that normally occurs during the first 2 weeks of the puerperium.

Radiographs are typically nonspecific. Ultrasonography is useful to identify uterine, adnexal, ovarian, pelvic, or hepatobiliary abnormalities and may diagnose appendicitis. Contrast-enhanced computed tomography (CT) is better for identifying appendicitis and complications of metritis such as septic pelvic thrombophlebitis.11,12

**HEMATOLOGIC**

**Hemorrhage**

Severe bleeding complications usually occur early in the puerperium. The most common cause of early postpartum hemorrhage is uterine atony. Because this complication usually occurs immediately after delivery of the placenta, it is not likely to be seen in the ED unless the mother delivered at home or at a birth center without medical backup.

The second most common cause of early postpartum bleeding is vaginal or cervical laceration of the reproductive tract. Sometimes these areas of bleeding can be concealed, especially if the source is above the pelvic diaphragm; they can be very uncomfortable and not obvious on examination.

Delayed bleeding is the hemorrhagic complication most likely to be evaluated in the ED. Most cases of delayed postpartum hemorrhage are associated with infected retained placental fragments or membranes. A persistently patent cervix, particularly if associated with bright red bleeding, should suggest retained products of conception.

A rare cause of hemorrhage (0.2 to 1 case per million) is an acquired hemophilia that usually occurs within the first
4 months after delivery, occasionally as early as the first postpartum day. The mortality from such hemorrhage is 12% to 22%. Of these patients, 54% have other previously diagnosed immune system diseases such as rheumatoid arthritis, systemic lupus erythematosus, and inflammatory bowel disease. A prolonged partial thromboplastin time with a normal prothrombin time localizes the coagulation defect to the intrinsic pathway of the coagulation cascade and thus suggests hemophilia as the cause of the hemorrhage.

Thromboembolic Complications
The index of suspicion for VTE should remain high because although complaints of dyspnea, tachypnea, leg swelling, and leg discomfort are common at term, they may also indicate PE or DVT. One study found that approximately 24% of women in whom DVT developed during pregnancy or the puerperium were asymptomatic and 55% complained of isolated leg swelling.4

DVT is best diagnosed by duplex ultrasonography because no radiation is involved; if the diagnosis is still uncertain, ultrasonography can be repeated or venography can be performed. To confirm the diagnosis of PE, ventilation-perfusion lung scanning or spiral CT could be performed safely in patients in the puerperium.

Neurologic embolic events such as cerebral embolism and cerebral venous thrombosis can also occur in the puerperium. Cerebral embolism generally involves the middle cerebral artery and is commonly associated with a cardiac arrhythmia, especially atrial fibrillation associated with rheumatic heart disease. However, these emboli may also be associated with rheumatic heart disease without arrhythmia, mitral valve prolapse, and infective endocarditis.

Central venous thrombosis is a rare but serious postpartum embolic complication with a frequency of 8.9 to 11.6 cases per 100,000 deliveries. The clinical findings are extremely variable and range from isolated headache to focal deficits to encephalopathy to psychiatric manifestations to coma.13 The diagnosis is made by brain imaging, commonly magnetic resonance imaging with gadolinium enhancement, magnetic resonance venography, magnetic resonance angiography, CT four-vessel angiography, CT angiography, or any combination of these modalities.

CARDIAC
Peripartum cardiomyopathy is a rare disorder that occurs in 1 of every 15,000 pregnancies in the United States, but it is a potentially fatal complication in the puerperium. Diagnostic criteria include onset of heart failure in the last month of pregnancy or in the first 5 months postpartum, absence of a determinable cause of the cardiac failure, absence of demonstrable heart disease before the last month of pregnancy, and impairment of left ventricular systolic function as demonstrated by echocardiography. The cause of peripartum cardiomyopathy is not known. Multiparity, multiple gestations, advanced maternal age (>30 years), preeclampsia, hypertension, and African descent are documented risk factors. The mortality associated with peripartum cardiomyopathy ranges from 18% to 56%.14 Survival is largely dependent on recovery of left ventricular function. Most who recover significant left ventricular function show improvement by 2 months after diagnosis.

Patients who fail to recover within 6 months may require cardiac transplantation. Those who undergo transplantation have a 30% higher rate of early rejection than do patients with idiopathic cardiomyopathy, but the survival rate at 2 years is 86%.15 Without transplantation, patients with persistent or progressive cardiomyopathy have a 5-year mortality rate approaching 50%.

Initial diagnostic evaluation includes electrocardiography, plain chest radiography, serum tests (electrolytes, liver function panel, complete blood count), and urinalysis. The electrocardiogram may be normal or tachycardic and may show nonspecific ST-segment or T-wave changes, atrial or ventricular dysrhythmias, left ventricular hypertrophy, PR or QRS prolongation, and conduction disturbances. Plain chest radiography usually shows cardiomegaly with pulmonary venous congestion and occasionally pleural effusion.

The diagnostic study of choice is echocardiography because it can be performed at the bedside, presents no radiation risk to pregnant patients, can differentiate between PE and amniotic embolism, and can provide prognostic information based on the degree of left ventricular dysfunction. The biggest drawback is often lack of availability in the ED.

Patients with peripartum cardiomyopathy are at especially high risk for thromboembolic events because of blood stasis from the severe left ventricular dysfunction, which may lead to left ventricular thrombi and subsequent emboli.

ENDOCRINE
Sheehan Syndrome
This syndrome of pituitary ischemia and necrosis associated with obstetric blood loss, first described in 1937, is an extremely rare occurrence in the developed world now that hemorrhage and shock are managed aggressively.

Thyroiditis
Postpartum thyroiditis is usually a self-limited autoimmune disorder marked by the development of postpartum thyroid dysfunction that occurs up to 9 months following delivery. Classically, a period of transient hyperthyroidism occurs between postpartum months 2 and 6, followed by a transient hypothyroid stage, with return to the euthyroid state by 1 year postpartum. Its incidence ranges from 1.1% to 16.7%.

Risk factors include the presence of thyroid antibodies, a previous episode of postpartum thyroiditis, type 1 diabetes mellitus, and a family history positive for thyroid disease. These patients have an increased risk for the development of permanent hypothyroidism in the following 5 to 10 years. The diagnosis is based on thyroid-stimulating hormone (TSH) levels and free triiodothyronine (T3) and thyroxine (T4) levels.

During the hyperthyroid state of postpartum thyroiditis, TSH is suppressed and free T3 and T4 levels are elevated. Symptoms include fatigue, palpitations, irritability, heat intolerance, and nervousness. Many of these symptoms are often attributed to the stress of motherhood, and the diagnosis is frequently missed. During the hypothyroid state, TSH is elevated with suppressed levels of free T3 and T4. Symptoms include impaired concentration, carelessness, lack of energy, poor memory, dry skin, cold intolerance, and aches and pains.

NEUROLOGIC
Headache is a common complaint in postpartum patients; it has been noted by about 15% of patients to occur in the first 2 weeks after delivery. The differential diagnosis of the cause of headache is extensive, and certain life-threatening
complications need to be excluded, such as central venous thrombosis, stroke, meningitis, and intracranial bleeding from an undiagnosed aneurysm or arteriovenous malformation. The patient’s personal and medical history is of the greatest importance to aid in diagnosis because it may suggest a cause such as migraine, post-dural puncture headache, or pneumocephalus.

The pain from pneumocephalus associated with epidural anesthesia is a result of direct injection of air into the subarachnoid space and is immediately felt as back pain at the level of needle insertion that spreads to the posterior aspect of the neck and then to the occipital and frontal areas. Generally, this complication, which occurs when the patient is in labor, resolves with supportive care, and the patient has no neurologic deficits.

Post-dural puncture headache is also associated with epidural anesthesia. It is a “nonthrobbing” headache that is worsened on change of posture from a horizontal to an upright position. These headaches are postulated to be caused by persistent loss of cerebrospinal fluid at a dural puncture site. Most of these headaches begin within 5 days of the procedure. Auditory and ocular symptoms may occur with prolonged or severe manifestations.

Other less common causes of headache in postpartum patients include central venous thrombosis (see the earlier section “Thromboembolic Complications”) and late postpartum preeclampsia, which may be manifested as hypertension with blood pressure greater than 140 mm Hg systolic and 90 mm Hg diastolic, proteinuria, and a headache not responsive to analgesics. Late postpartum eclampsia occurs in 3% to 26% of eclamptic patients. Late postpartum preeclampsia or eclampsia is defined as the development of signs and symptoms after 48 hours and before 4 weeks following delivery. Most patients with postpartum preeclampsia or eclampsia do not have a preceding history of gestational preeclampsia or eclampsia. A postpartum woman with a new history of convulsions occurring more than 48 hours after delivery plus proteinuria and hypertension should be considered eclamptic while other causes are being ruled out. Neuroimaging generally demonstrates a posterior reversible encephalopathy syndrome.

**PSYCHIATRIC**

Fatigue is one of the most common complaints during the puerperium. Some fatigue is normal given the demands of taking care of a newborn infant after the physical rigors of labor and delivery; however, this complaint should be taken seriously because it can be the first symptom of anemia, new-onset diabetes, hypothyroidism, or a psychiatric disorder.

The most common postpartum mood disturbance is the postpartum blues, which affects 50% to 80% of new mothers. Physicians must evaluate the patient to differentiate postpartum blues from the more severe symptoms associated with postpartum depression. Up to 20% of women with postpartum blues will have a major depressive episode in the first postnatal year. Multiple risk factors for postpartum depression have been identified: personal or family history of depression, previous episode of postpartum depression, depression or anxiety during pregnancy, an unplanned or unwanted pregnancy, recent stressful life events, poor social support, and marital discord. Neonatal medical problems or the occurrence of postpartum blues also increases the risk for postpartum depression.

Usually beginning within the first 4 weeks after delivery, postpartum depression is highly variable in severity and duration. It occurs in 5% to 20% of new mothers and is especially prevalent in adolescent mothers. The diagnosis of depression is difficult to make in a postpartum mother because the typical signs and symptoms have significant overlap with normal issues of the puerperium, such as disturbances in sleep, weight, and energy.

The most severe form of psychiatric disease in the postpartum period is postpartum psychosis. Fortunately, this condition is rare and occurs in fewer than 2 of every 1000 deliveries. The onset of postpartum psychosis is usually within the first 3 weeks after delivery and occasionally within a few days after delivery. Many of these patients have a history of schizophrenia or bipolar disorder. Symptoms include delusions, hallucinations, rapid mood swings, sleep disturbances, and obsessive thoughts about the baby.

---

**TREATMENT AND FOLLOW-UP**

**GENITOURINARY**

**Metritis and Pelvic Infections**

Low-risk patients in whom mild metritis develops after being sent home following vaginal delivery can be treated with an oral microbial agent such as doxycycline or azithromycin. Patients with moderate to severe metritis, as well as those who have delivered by cesarean section, should be treated with broad-spectrum intravenous antibiotics to cover mixed flora and should be observed in the hospital.

Most patients should improve with antibiotics within 48 to 72 hours, and failure to improve suggests a complication of metritis such as parametrial phlegmon, pelvic or incisional abscess, infected hematoma, septic pelvic thrombi, retention of fetal parts, or bacteria resistant to the treatment regimen.

Treatment of pelvic abscesses includes intravenous antibiotics and possible percutaneous drainage. In cases of septic pelvic thrombi, intravenous antibiotics are currently the mainstay of therapy because studies indicate that the use of heparin does not alter the outcome.

Empiric treatment of necrotizing fasciitis varies widely. Treatment typically consists of a four-antibiotic regimen that includes gram-positive coverage with a penicillin or extended-spectrum penicillin; gram-negative coverage with aminoglycosides, cephalosporins, or carbapenems; anaerobic coverage with clindamycin; empiric coverage for methicillin-resistant *S. aureus* (MRSA) such as vancomycin; and emergency operative débridement of the area.

**Toxic Shock Syndrome**

Treatment of TSS includes aggressive fluid management with crystalloids, supportive care, and pressors as needed. Antibiotics do not alter the course of TSS, but they decrease the recurrence rate by 50%. An agent to cover gram-positive organisms plus coverage for MRSA, such as vancomycin combined with an aminoglycoside such as gentamicin, is appropriate.

**Perineal Pain**

Early application of cold compresses or ice packs to soft tissue trauma reduces swelling and discomfort. Sitz baths are also recommended to alleviate discomfort. Acetaminophen or
nonsteroidal antiinflammatory drugs (generally considered safe in breastfeeding patients) are the initial medications of choice for pain.

**Urinary Tract Dysfunction**

Most patients with urinary retention will note incomplete voiding and will not require catheterization, but they should be referred to the urology or urogynecology department for urodynamic testing.

Stress urinary incontinence is another complaint that occurs in the postpartum period. The ED usually lacks the facilities to address this complaint, but these patients should be referred to the urology or urogynecology department for work-up and management.

**LACTATION AND BREAST DYSFUNCTION**

**Breast Engorgement**

During the state of engorgement, breast pain can be partially alleviated by a supportive brassiere or breast binder, avoidance of nipple stimulation, ice packs, and oral analgesics.²⁻⁶

**Galactocele**

Warm compresses may help the situation resolve spontaneously, but in patients with a large amount of pain and fluctuance, needle aspiration may be required.

**Mastitis**

First-line agents for the treatment of mastitis are penicillin, cephalosporin, clindamycin, and erythromycin (for penicillin-sensitive patients); all are considered safe in lactating women. The infection should show improvement within 48 hours. Lack of improvement over this period suggests an abscess or resistant organism. Abscesses require incision and drainage with packing or ultrasound-guided needle aspiration, which has a success rate of 80% to 90%.

If resistant organisms are suspected, milk from the affected breast should be sent on a swab for culture, and an antimicrobial agent effective against MRSA should be started. Continued breastfeeding on the affected side is important to help clear the infection. If the baby is having difficulty latching on because of surrounding erythema or induration, the affected breast can be pumped gently. Patients should be referred for a follow-up visit within 72 hours to their primary care physician or gynecologist to ensure that they are responding to the medication prescribed.

**HEMATOLOGIC**

**Postpartum Bleeding**

Treatment consists of broad-spectrum antibiotics and emergency obstetric consultation for dilation and curettage. Disseminated intravascular coagulation can occur in these cases and may require aggressive management with platelets, fresh frozen plasma, and packed red blood cells.¹

Hemorrhage from acquired hemophilia should prompt a hematology consultation. Management of the hemorrhage consists of the administration of blood products to replace the blood loss, coagulation factor, and immunosuppressants. Selection of a product for control of acute bleeding depends on the clinical severity and on coagulation factor VIII inhibitor titers. Immunosuppressive therapy with corticosteroids and cytotoxic drugs, alone or in combination, has been the mainstay of therapy in stable patients. In most of these cases, the acquired hemophilia spontaneously remits within months of delivery.²⁰

**Deep Vein Thrombosis**

Treatment of postpartum patients with DVT consists of unfractionated or low-molecular-weight heparin and transition to warfarin (Coumadin), which is safe in lactating patients because it does not significantly cross over into breast milk.²⁻²¹

**Central Venous Thrombosis**

Management includes anticonvulsants to control seizures, emergency neurology consultation, and antimicrobials if septic thrombosis is suspected. Heparin therapy is controversial because of the bleeding complications that may develop.⁶

**CARDIAC**

Treatment of postpartum cardiomyopathy is the same as that for nonischemic dilated cardiomyopathy. Management should be supportive with restriction of sodium (no more than 4 g daily of salt) and fluid (no more than 2 L of daily fluid intake). Preload- and afterload-reducing agents plus positive inotropic agents, if the patient is acutely ill, are the cornerstones of treatment. For antepartum patients, afterload reduction can be accomplished with hydralazine; positive inotropy with digoxin; and preload reduction with diuretics, nitroglycerine, and beta-blockers. Postpartum patients should receive angiotensin-converting enzyme inhibitor therapy, which has been shown to improve survival in patients with dilated cardiomyopathy.¹⁸ Breastfeeding mothers should curtail breastfeeding because angiotensin-converting enzyme inhibitors are excreted in breast milk and their safety is unproved.²²

**ENDOCRINE DISORDERS**

**Thyroiditis**

Most women in the hyperthyroid stage need no treatment or intervention. Symptomatic patients in this stage can usually be managed with beta-blockers and referral to an endocrinologist. The hypothyroid stage is multifactorial, and management is more difficult; these patients should also be referred to an endocrinologist for long-term follow-up. Patients with a TSH level greater than 10 mU/L or who are symptomatic with a TSH level greater than 10 mU/L should be treated with levothyroxine. Women who are planning to become pregnant again should be cautioned to wait until they have discussed the issue with an endocrinologist because even subclinical hypothyroidism can cause an increased miscarriage rate and may result in impaired cognitive performance in the child.²²

**NEUROLOGIC**

Headaches that result from the pneumocephalus associated with epidural anesthesia generally occur when the patient is in labor and resolve with supportive care.¹³

Treatment of post–dural puncture headaches includes hydration and analgesic agents initially. If these measures fail, an anesthesia consultation to consider an epidural blood patch is recommended.¹⁶⁻²³

Postpartum preeclampsia or eclampsia can develop as late as 2 or more weeks postpartum. Magnesium sulfate therapy should be initiated with a loading dose of 4 g administered over a 30-minute period, followed by a maintenance dose of 2 g/hr for at least 24 hours after the last seizure, along with close monitoring and observation. More detail about the
diagnosis and management of these patients can be found in Chapter 121.

PSYCHIATRIC
Postpartum blues is generally a self-limited and benign condition, but patients should be evaluated for a personal or family history of depression, as well as the strength of their social support structure. Patients with postpartum blues should be referred to their primary care physicians for follow-up. Those with risk factors for a major depressive episode should be educated about the signs and symptoms of major depression and be encouraged to seek help if they experience these symptoms. Patients who show signs of psychosis or major depression require psychiatric evaluation and follow-up before they can be discharged. Patients with postpartum psychosis require emergency hospitalization because 5% of these patients commit suicide and 4% commit infanticide.24

PATIENT TEACHING TIPS
After starting antibiotics for mastitis, improvement should be seen by 48 to 72 hours; if the condition does not improve or worsens, an abscess or resistant organism may be the cause of the infection, and reevaluation is necessary. Patients with mastitis should be instructed to continue breastfeeding on the affected side to help clear the infection.
To avoid complications in a second pregnancy, patients with hypothyroidism should not become pregnant again until management of the disorder is successful and cleared by an endocrinologist.
Patients with abdominal pain should be counseled on the difficulty of making intraabdominal diagnoses in the puerperium and should have clear follow-up and return visit instructions.
Patients with postpartum blues should be reassured that this is normal and usually resolves within a few days. If no improvement in symptoms is seen by the end of a week, patients should be reevaluated either in the emergency department or by a psychiatrist.

DOCUMENTATION
The mode of delivery is an important factor in puerperium complications; delivery by cesarean section is associated with higher rates of infection, as well as other disorders. Note the method of delivery, pregnancy and delivery complications, and associated risk factors.
Document social support for the patient and infant.
Give and record instructions about potential complications.
Patients with abdominal pain are at increased risk for complications; provide clear instructions on where and when follow-up should be carried out, list reasons to return to the emergency department, and discuss potential causes of abdominal pain.
In patients with headache in the first 3 postpartum weeks, document the timing of the headache, worsening with change of position, and quality of the headache.

Gynecologic Pain and Vaginal Bleeding

Jamie L. Collings and Nicholas A. Borm

VAGINAL FOREIGN BODY

The epidemiology of vaginal foreign bodies is largely unknown, but one study theorizes that approximately 20% of preteenage girls with vaginal bleeding with or without discharge and 50% of those with bleeding and no discharge will prove to have vaginal foreign bodies.

ENDOMETRIAL CANCER

Endometrial cancer is the fourth most common cancer in women and occurs in approximately 25 per 100,000 women.5,6 This malignant disease develops during the reproductive and menopausal years, with most patients being 50 to 59 years of age. About 5% of women younger than 40 have adenocarcinoma, and it is diagnosed in a quarter of patients before menopause. Many cases of endometrial cancer go undetected given that Papanicolaou smears detect only 50% of cases and the diagnosis is rarely considered in perimenopausal women despite the aforementioned statistics.

CERVICAL CANCER

Cervical cancer is the second most common malignancy in women worldwide. Approximately 11,000 new cases are diagnosed annually in the United States, and it accounts for around 4000 deaths per year. Minority populations are more commonly affected. The peak incidence of cervical cancer occurs in women 45 to 54 years of age; however, there is a surge in prevalence in women in their 20s and 30s as human papillomavirus (HPV) rates have increased.5,6

PATHOPHYSIOLOGY

Common terminology and definitions for vaginal bleeding are listed in Box 124.1. An understanding of the normal female reproductive cycle is useful when caring for patients with vaginal bleeding and pelvic pain. The normal reproductive cycle is 28 days, with a range of 21 to 35 days, and the average age at menarche is approximately 12.5 years. The complex hormonal feedback mechanism that governs the female reproductive cycle is controlled by the hypothalamic-pituitary-ovarian (HPO) axis. Days 1 to 14 are known as the follicular or proliferative phase and are dominated by the release of gonadotropin-releasing hormone (GnRH) from the hypothalamus; GnRH in turn stimulates pituitary release of follicle-stimulating hormone (FSH). During this phase a dominant ovarian follicle matures and produces estrogen, which causes the poss

---

VAGINAL BLEEDING

This section of the chapter addresses common causes of vaginal bleeding, including dysfunctional uterine bleeding (DUB), uterine leiomyomas (fibroids), vaginal foreign body, endometrial cancer, and cervical cancer.

EPISTEMOLOGICAL

DYSFUNCTIONAL UTERINE BLEEDING

DUB affects an estimated 30% of women in the United States, is most common at the extremes of the reproductive years, and has no predilection for race. DUB rarely causes mortality but is accountable for two thirds of all hysterectomies and the majority of endoscopic endometrial destructive surgery.1

UTERINE LEIOMYOMAS (FIBROIDS)

Uterine leiomyomas (fibroids) are the most common pelvic tumor in women and have been noted on pathologic examination in approximately 80% of surgically excised uteri.2 Risk factors include African American race, early menarche (<10 years of age), nulliparity, and family history. Several studies have shown more subtle correlations with obesity and diet.3,4

---

KEY POINTS

- The possibility of pregnancy should be considered in every patient with a chief complaint of vaginal bleeding or pelvic pain.
- Ectopic pregnancy, acute appendicitis, and ovarian torsion must be considered in female patients with acute pelvic pain.
- Up to 50% of patients with ovarian torsion have normal findings on ultrasound.
- Malignancy should be considered in postmenopausal women with new-onset vaginal bleeding.
- With the exception of physiologic withdrawal bleeding in the neonate, vaginal bleeding in a prepubescent girl is always abnormal.
Pelvic pain or abnormal vaginal bleeding. Layers of the endometrium, and thus menstruation occurs. Prostaglandins are released and cause vasospasm within the endometrial vasculature. This leads to sloughing of the outer endometrium. Gesterone levels drop at the end of the secretory (luteal) phase, which induces maturation of the endometrium. If conception continues past the cessation of menses.

Changes in the endometrium occur at each step of the reproductive cycle. During the proliferative phase the endometrium grows and thickens in response to estrogen as it prepares for implantation of an embryo. During the secretory phase the endometrium matures under the influence of progesterone and glands and secretory vacuoles develop. As progesterone levels drop at the end of the secretory (luteal) phase, prostaglandins are released and cause vasospasm within the endometrial vasculature. This leads to sloughing of the outer layers of the endometrium, and thus menstruation occurs.

Disruption at any point in this feedback loop may cause pelvic pain or abnormal vaginal bleeding.

**DYSPNERSAL UTERINE BLEEDING**
DUB is the most common cause of menorrhagia in menstruating females and is defined as abnormal uterine bleeding in the absence of organic disease. DUB can be ovulatory or anovulatory. Ovulatory DUB is hallmarked by regular intervals of increased menstrual flow. The root cause is an abnormality in the uterine hemostasis secondary to cytokine and prostaglandin production. More commonly (accounting for 90% of cases of DUB), anovulatory DUB is hallmarked by irregular intervals of alternating heavy and light flow. This can be caused by primary ovarian disorders or a disruption in the HPO axis.

Polycystic ovarian disease is classically associated with anovulatory uterine bleeding. It is defined by ovulatory failure, which leads to the absence of a corpus luteum and thus the lack of progesterone production and therefore unopposed action of estrogen on the endometrium. The uterine lining persists in the proliferative phase until it outgrows its vascular supply and degenerates, thereby leading to irregular menses with alternation between heavy and light flow. Women often have signs of hyperandrogenism, including hirsutism, obesity, acne, palpable enlarged ovaries, and acanthosis nigricans (hyperpigmentation typically in the folds of the skin of the neck, groin, or axilla).

Anovulatory DUB is most commonly seen in postpubescent girls secondary to immaturity of hypothalamic function. In general, it is failure to mount an LH surge that causes this dysfunction. As the central nervous system matures, the menses are ultimately regulated. In addition, systemic disease such as thyroid disorders, extreme fluctuations in weight, excessive exercise, or stress can all disrupt the HPO axis and lead to anovulation.

**UTERINE LEIOMYOMAS (FIBROIDS)**
Uterine leiomyomas are benign tumors arising from the myometrium that ultimately disrupt the normal contour of the endometrium. Abnormal uterine bleeding is the most common symptom and is usually manifested as chronic heavy and prolonged menses, or menometrorrhagia. The location of the myomas seems to determine the majority of the symptomatology, whereas size is of secondary importance.

The disease process just described generally occurs in the fourth decade of life and usually abates after menopause. Approximately 10% to 40% of fibroids will regress over a period of 6 months to 3 years, and almost all symptomatology will abate at the time of menopause because these uterine tumors are estrogen sensitive. With the use of postmenopausal hormone replacement therapy, however, symptoms may continue past the cessation of menses.

**VAGINAL FOREIGN BODY**
Vaginal foreign bodies can lead to vaginal bleeding secondary to direct trauma, local irritation, superimposed infection, or any combination of these causes. The two most common foreign bodies are toilet tissue (minors) and tampons, although a wide range of vaginal foreign bodies have been reported.

**ENDOMETRIAL CANCER**
Risk factors for the development of endometrial cancer include age older than 35 years, history of anovulatory cycles, nulliparity, obesity, tamoxifen therapy, exogenous estrogen use without progestins, and diabetes mellitus. Almost all these

The endometrium to thicken and prepare for possible embryo implantation. Positive feedback of estrogen to the pituitary gland induces a surge in luteinizing hormone (LH) on day 14 of the cycle, which results in ovulation. Days 14 to 28 are known as the luteal or secretory phase; this phase is predominated by progesterone production from the corpus luteum, which induces maturation of the endometrium. If conception and implantation do not occur, the corpus luteum involutes, estrogen and progesterone levels fall, and menstruation occurs.

Changes in the endometrium occur at each step of the reproductive cycle. During the proliferative phase the endometrium grows and thickens in response to estrogen as it prepares for implantation of an embryo. During the secretory phase the endometrium matures under the influence of progesterone and glands and secretory vacuoles develop. As progesterone levels drop at the end of the secretory (luteal) phase, prostaglandins are released and cause vasospasm within the endometrial vasculature. This leads to sloughing of the outer layers of the endometrium, and thus menstruation occurs.

Disruption at any point in this feedback loop may cause pelvic pain or abnormal vaginal bleeding.
risk factors are associated with elevated levels of estrogen or prolonged exposure to estrogen.

**CERVICAL CANCER**
Risk factors for cervical cancer are strongly correlated with sexual activity and include multiple sexual partners, early age at first coitus, early pregnancy, and previous history of sexually transmitted diseases. All these risk factors increase exposure to HPVs, which have been implicated as a major risk factor for the development of cervical cancer and high-risk lesions.

**PRESENTING SIGNS AND SYMPTOMS**

Vaginal bleeding can vary greatly in amount and severity. A thorough history and physical examination should be performed to evaluate the onset, duration, amount, and timing within the menstrual cycle of the bleeding. Assessment of severity includes determining the number of tampons or pads changed over a 12- to 24-hour period, whether they were saturated, and whether any clots were associated with the bleeding. Associated symptoms such as orthostatic complaints, fatigue, and dyspnea on exertion should point to underlying anemia from chronic blood loss or hypovolemia from acute blood loss. Vaginal bleeding may not be the primary disorder, and thus a thorough search for causes of secondary vaginal bleeding is prudent. The age of the patient, medical and surgical history, and medication profiles will also provide clues to the cause of the bleeding.

**DYSFUNCTIONAL UTERINE BLEEDING**
The typical finding of DUB is irregular menses with alteration between heavy and light flow. Women often have signs of hyperandrogenism, including hirsutism, obesity, acne, palpable enlarged ovaries, and acanthosis nigricans (hyperpigmentation typically in the folds of the skin of the neck, groin, or axilla).

**UTERINE LEIOMYOMAS (FIBROIDS)**
The symptoms that arise from uterine myomas can be classified into abnormal uterine bleeding, pelvic pressure and pain, and reproductive dysfunction. The number, size, and location of these tumors dictate the severity of symptoms. Abnormal uterine bleeding is the most common symptom and is usually manifested as chronic heavy and prolonged menses, or metrorrhagia. Bulk-related symptoms of fibroids include urinary frequency, difficulty voiding, urinary obstruction, constipation, and occasionally back pain. In addition, leiomyomas have the propensity to degenerate or twist on their stalk and cause torsion. In this setting, pelvic pain may be accompanied by low-grade fevers, uterine tenderness, leukocytosis, or even peritoneal signs. Distortion of the uterine cavity secondary to leiomyomas may result in difficulty conceiving and has been associated with an increased risk for miscarriage, placental abruption, fetal growth restriction, and preterm labor.

**VAGINAL FOREIGN BODY**
Mild vaginal bleeding may be the initial sign in a patient with a retained vaginal foreign body. If associated with infection, the patient may also have a purulent discharge or vaginal irritation.

**ENDOMETRIAL CANCER**
Symptoms include painless postmenopausal vaginal bleeding. In perimenopausal patients, the menses typically lighten and become farther apart. Heavy or frequent menstrual periods or intermenstrual bleeding in this patient population should be evaluated.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**
The first step in evaluating any woman with vaginal bleeding should be to determine whether the patient is pregnant because this will drastically alter the diagnostic and therapeutic approach.

The most common causes of abnormal vaginal bleeding in nonpregnant females are DUB and uterine leiomyomas. Tables 124.1 and 124.2 list the differential diagnosis of vaginal bleeding in nonpregnant females. Figure 124.1 details an approach to patients seen in the emergency department (ED) with the complaint of vaginal bleeding.

**DYSFUNCTIONAL UTERINE BLEEDING**
The majority of the work-up for DUB, including laboratory analysis and diagnostic imaging, is completed in the outpatient setting. However, several critical actions should be done by an emergency physician (EP) when these patients are encountered in the ED. Initial screening in appropriate patients includes human chorionic gonadotropin because the most common cause of abnormal uterine bleeding during the pregnancy is miscarriage, placental abruption, fetal growth restriction, and preterm labor.

reproductive years is an abnormal pregnancy. Once pregnancy is ruled out, further laboratory testing and diagnostic imaging can be tailored to each particular patient.

Complete blood count analysis is prudent in most patients with abnormal vaginal bleeding and can both provide analysis for anemia and establish a baseline hemoglobin and hematocrit level for the patient. Further laboratory analysis could include thyroid function tests and prolactin levels because these abnormalities are associated with ovulatory dysfunction. If significant bleeding is a concern, liver function tests and coagulation factor assay should be performed because hepatic disease and inborn errors of coagulation can complicate abnormal vaginal bleeding.

The mainstay of imaging for patients with abnormal vaginal bleeding is pelvic ultrasonography. Ultrasound imaging can be helpful in evaluating the status of the endometrium to look for hyperplasia, carcinoma, polyps, and uterine fibroids and, if available, can direct treatment and follow-up care for the EP.

**UTERINE LEIOMYOMAS (FIBROIDS)**
The diagnosis of fibroids is based on the physical examination finding of an enlarged, mobile uterus with irregular contours in combination with pelvic ultrasound imaging. It is important that the physician keep a broad differential diagnosis when identifying a new uterine mass because both benign and malignant lesions may be manifested similarly. Other conditions characterized by an enlarged uterus include pregnancy, adenomyosis, hematometra, uterine sarcoma, uterine carcinosarcoma, endometrial carcinoma, and metastatic disease.

Transvaginal ultrasound remains the primary imaging modality in this patient population. This study has high sensitivity (95% to 100%) for detecting myomas in mild to moderate cases of uterine enlargement. Other imaging modalities include diagnostic hysteroscopy, magnetic resonance imaging (MRI), and hysterosalpingography.

**VAGINAL FOREIGN BODY**
Once a vaginal foreign body is suspected, a thorough gynecologic examination, including a speculum and bimanual examination, should be completed. The physician should make every attempt to identify secondary injury from the foreign body and intervene as necessary.

If secondary systemic infection is a concern, urgent laboratory testing and diagnostic imaging should take place to evaluate for end-organ injury. Testing may include laboratory tests such as a complete blood count, chemistry panel, lactate analysis, and blood cultures. Diagnostic tools such as plain film radiographs or computed tomography (CT) scans of the abdomen and pelvis may be indicated depending on the severity of the symptoms.

**ENDOMETRIAL CANCER**
No specific laboratory testing is necessary in the ED setting to evaluate for endometrial adenocarcinoma. As with all vaginal bleeding, assessment of the patient and the need for a complete blood count analysis and other laboratory testing founded on a differential diagnosis is done on a case-by-case basis.

**CERVICAL CANCER**
Again, no specific laboratory testing is necessary in the ED setting to evaluate for cervical cancer. The patient may need a complete blood count analysis and other laboratory testing...

**TREATMENT**

**DYSFUNCTIONAL UTERINE BLEEDING**

Oral contraceptive pills (OCPs) remain first-line therapy for DUB. OCPs suppress endometrial development, reestablish predictable bleeding patterns, decrease menstrual flow, and lower the risk for iron deficiency anemia. Treatment can be effective in either a cyclic or continuous regimen, and many gynecologists recommend tapering of OCPs over 1-week period to control acute blood loss in patients with DUB. The typical regimen includes low-dose OCPs two to three times daily for 7 days, 7 days off for withdrawal bleeding, followed by once-daily OCP use for 3 months. Single-agent therapy with estrogen or progesterone alone is used in selected cases and is best prescribed with gynecologic consultation.

If significant hemorrhage from a uterine source is leading to hemodynamic instability, the physician must consider a primary bleeding disorder. In this case, laboratory analysis should focus on identification of disseminated intravascular
coagulation, thrombocytopenia, or inherited coagulopathies with a focus on repletion of blood products as necessary and prompt gynecologic consultation. In certain cases, desmopressin has been shown to be effective in controlling hemorrhage because it rapidly increases von Willebrand factor and factor VIII with duration of action lasting about 6 hours.

In these extreme cases or in patients with medical failure, surgical intervention may be necessary, including dilation and curettage or endometrial ablation; if all else fails, abdominal hysterectomy may be indicated.

UTERINE LEIOMYOMAS (FIBROIDS)
Treatment of leiomyomas is generally initiated when the tumors become symptomatic and is dependent on size, location, severity, age, and reproductive plans. OCPs again are the first-line treatment for medical management; however, although they may work well in regulating abnormal uterine bleeding, they are not very effective in reducing the bulk symptoms. More effective at medical management of fibroids are GnRH agonists. They work by causing an increase in the release of gonadotropins, which in turn desensitizes and downregulates the reproductive tissue and thus causes a hypo-gonadal state. Most women will experience amenorrhea and a significant reduction (35% to 60%) in uterine size within 3 months of initiation of therapy. Even though these medications are quite effective, initiation of therapy should be guided by a gynecologist, and they are rarely started in the ED setting. The addition of nonsteroidal antiinflammatory drugs (NSAIDs) is useful in this population to regulate painful menses, but they do not have much action on uterine bleeding.

Surgical intervention is the definitive treatment of uterine myomas, which is the most common indication for hysterectomy. Hysterectomy is reserved for patients with acute hemorrhage that does not respond to medical management, women with increased risk for malignancy, those in whom minimally invasive procedures fail, or patients who no longer wish to preserve fertility. Several minimally invasive procedures such as myomectomy, endometrial ablation, or uterine artery embolization have increased in popularity and can be used in patients who wish to retain their uterus or have not yet completed childbearing.

VAGINAL FOREIGN BODY
Generally, prompt removal of the foreign body will result in resolution of the patient’s symptoms and is often the only intervention necessary. If toxin-mediated disease such as toxic shock syndrome is suspected, urgent administration of antibiotics is paramount and lifesaving. An antibiotic regimen targeted against staphylococcal and streptococcal species is prudent and should be augmented with clindamycin because it is a potent suppressor of the synthesis of bacterial toxin.

ENDOMETRIAL CANCER
Depending on the histopathology noted on endometrial biopsy and staging of the cancer, surgical or chemotherapeutic interventions may be initiated.

CERVICAL CANCER
As with other gynecologic malignancies, the primary role for the EP is timely recognition and referral to a gynecologic specialist who can arrange for a Papanicolaou test, colposcopy, directed biopsies, and endocervical curettage. Surgical, radiation, or chemotherapeutic interventions are tailored to the stage of cervical cancer and directed by specialty care.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION
Any patient with vaginal bleeding and evidence of symptomatic anemia or hypovolemia should be admitted for definitive treatment and observation. However, the majority of patients with the diseases mentioned in this section can be treated and managed as outpatients with strong emphasis on gynecologic follow-up.

As an outpatient, a patient with abnormal vaginal bleeding may undergo further testing, including a Papanicolaou smear, endometrial sampling, hormonal assays, or hysteroscopy, and can be managed by a practicing gynecologist. Most patients should be referred for follow-up, continued treatment, or further diagnostic evaluation, depending on the findings or concerns addressed in the ED.

PELVIC PAIN
This section of the chapter focuses on gynecologic causes of pelvic pain, including ovarian torsion, ovarian cysts, ovarian tumors, and endometriosis. Other causes of pelvic pain are covered in other sections of this textbook.

EPIDEMIOLOGY

OVARIAN TORSION
Ovarian torsion is the fifth most common gynecologic surgical emergency, and because of vague, nonspecific findings, the diagnosis is usually delayed, which can result in necrosis of the ovary and poor salvage rates. Several studies have reported salvage rates as low as 10% to 25%. Adnexal torsion can occur at any age, but the highest incidence is in the early reproductive years, with approximately 80% of cases occurring in those younger than 50 years.

OVARIAN CYSTS
Ovarian cysts are estimated to affect 7% to 10% of premenopausal and postmenopausal woman. Up to 4% of women will be admitted to the hospital with a primary diagnosis of ovarian cysts. Approximately 3% of theca lutein cysts are complicated by torsion or hemorrhage, and approximately 30% of these cysts can cause maternal androgen excess. Ovarian cysts affect all age ranges of females, from those in utero to postmenopausal women.

OVARIAN TUMORS
Ovarian cancer is the most common cause of death from gynecologic tumors in the United States. Worldwide, the reported lifetime risk for the development of ovarian malignancy is 1 in 70, and it accounts for 100,000 deaths annually. Ovarian cancer affects white women more than black women, and the incidence increases with age. The mean age of females...
with ovarian carcinoma is 56. The overall prognosis for ovarian cancer is poor, with reported 5-year mortality rates reaching 46%, but it is closely related to staging. In girls younger than 9 years, 80% of ovarian masses are malignant, with the majority being germ cell tumors. These tumors are generally localized to the ovary and have cure rates of 90% after chemotherapy.

ENDOMETRIOSIS

Endometriosis is commonly a disease of reproductive-age women, with the highest incidence of disease in those 25 to 35 years of age. It is uncommon in prepuberal girls and postmenopausal women who are not receiving estrogen replacement therapy. The disease is reported to occur in approximately 7% to 10% of the general population of women and is found in 20% to 50% of infertile women and 80% of women with chronic pelvic pain. There is a strong familial relationship, with the incidence in women who have an affected first-degree relative being significantly increased.¹⁶,¹⁷

PATHOPHYSIOLOGY

Causes of gynecologic pelvic pain in nonpregnant females can be divided into infectious, ovarian, cervical, uterine, or extraterine. As with vaginal bleeding, an understanding of the female reproductive cycle is paramount in understanding the pathophysiology of disease.

OVARIAN TORSION

Ovarian torsion is caused by mechanical obstruction of the vascular supply to the ovary, and progressive edema and eventually necrosis ensue if the torsion is untreated.

Classically, ovarian torsion occurs unilaterally in a pathologically enlarged ovary, almost always secondary to a cyst or neoplasm. Approximately 80% of cases of torsion occur in ovaries that are 5 cm or larger, and it occurs on the right more than on the left. In young children, ovarian torsion may develop in a normal ovary secondary to developmental abnormalities such as a long fallopian tube or absent mesosalpinx. Pregnancy is a strong risk factor for ovarian torsion because of the corpus luteum increasing the ovarian mass, and it is responsible for approximately 20% of cases. Ovarian tumors and pelvic surgery also increase the risk for torsion, and it has even occurred in patients following laparoscopic hysterectomy.

OVARIAN CYSTS

Different kinds of functional ovarian cysts can form during the menstrual cycle. Follicular cysts may result from lack of physiologic release of the ovum because of excessive FSH stimulation or from lack of the normal LH surge at midcycle just before ovulation. Hormonal stimulation causes these cysts to continue to grow. Follicular cysts are typically larger than 2.5 cm in diameter.

In the absence of pregnancy, the life span of the corpus luteum is 14 days. If the ovum is fertilized, the corpus luteum continues to secrete progesterone for 5 to 9 weeks until its eventual dissolution in 14 weeks, when the cyst undergoes central hemorrhage. Failure of dissolution to occur may result in a corpus luteal cyst, which is arbitrarily defined as a corpus luteum that grows to 3 cm in diameter.

Theca lutein cysts are caused by luteinization and hyper-trophy of the theca interna cell layer in response to excessive stimulation of β-human chorionic gonadotropin. This type of cyst can occur in the setting of gestational trophoblastic disease, multiple gestation, or exogenous ovarian hyperstimulation. Theca lutein cysts are usually bilateral and result in massive ovarian enlargement.

OVARIAN TUMORS

The peak incidence of ovarian tumors occurs at 55 to 65 years of age; however, the majority of ovarian masses in children are malignant. Consequently, a palpable ovary in a postmeno-pausal woman or prepubescent girl should be considered a malignancy until proved otherwise. Risk factors include frequent ovulation, nulliparity, late menopause, family history, and late childbearing age. Oral contraceptives are believed to decrease risk for the development of ovarian malignancies.

Epithelial tumors represent the most common histologic type (90%), with other causes including sex cord stromal tumors, germ cell tumors, and metastatic disease. These tumors appear as partially cystic lesions with solid components.¹⁸ Metastatic disease is often found on the peritoneal surfaces but can be found in the liver, small bowel, uterus, lymphatic system, and lungs. In the prepubescent population, germ cell tumors are the most common histologic type, and the risk for teratomas increases into adolescence.

ENDOMETRIOSIS

Endometriosis is defined as the presence of endometrial tissue in a location outside the uterine cavity and can be definitively diagnosed only by direct visualization via laparoscopy. There is no clear-cut explanation for the pathogenesis of endometriosis; however, several hypotheses have been proposed, including retrograde menstruation, surgical transplantation, lymphatic or hematogenous spread, cellular metaplasia, altered immunity, or genetic disposition.

The most common sites are ovarian and dependent portions of the pelvis, including the ovaries, broad ligament, fallopian tubes, sigmoid colon, and appendix. Endometriosis can sometimes be found outside the pelvis and has been reported in the breast, pancreas, liver, kidney, vertebrae, and lung.

PRESENTING SIGNS AND SYMPTOMS

Pelvic pain may be acute or chronic. Acute pain should raise concern for a life-threatening or organ-threatening process that may warrant urgent treatment or intervention. Chronic pain is more likely to represent an indolent process such as scarring or malignancy. A good history and complete physical examination focusing on the abdomen and genitourinary system will provide great insight into possible causes of the pain. Paying close attention to age, past medical and surgical history, sexual history, and timing in the reproductive cycle will further narrow the differential diagnosis.

OVARIAN TORSION

The typical finding is an acute onset of unilateral pelvic pain that can be intermittent and associated with nausea and vomiting. Approximately 25% of patients experience bilateral lower quadrant pain, and as many as 70% of patients have an element of nausea and vomiting that can often mimic a gastrointestinal
cause. Fever is evidence that necrosis of the tissue has occurred.

Findings on physical examination are traditionally nonspecific and variable. Bimanual examination will reveal a tender adnexal mass or fullness in between 50% and 90% of patients. However, absence of this finding should not exclude this diagnosis. Peritonitis usually occurs late in the disease process.

**OVARIAN CYST**

Ruptured cysts may cause an acute onset of unilateral pelvic pain and can mimic ovarian torsion or acute appendicitis. They usually occur in the second half of the menstrual cycle and begin during strenuous physical activity. Though rare, other associated symptoms may be present, including vaginal bleeding, nausea and vomiting, syncope, orthostatic changes, shoulder pain, and circulatory collapse.

**OVARIAN TUMORS**

Ovarian tumors may be accompanied by abnormal vaginal bleeding secondary to hormone secretion; however, they generally cause signs and symptoms related to a mass effect. Patients are often asymptomatic, and ovarian tumors are commonly found during evaluation or imaging for an unrelated issue. Adults generally have typical bulk-related complaints, including urinary frequency, constipation, rectal fullness, pelvic pressure, and bloating. Conversely, the pediatric population will generally have pelvic pain initially.

**ENDOMETRIOSIS**

The sometimes diffuse pelvic pain caused by endometriosis is cyclic and estrogen responsive. Pain is the most common initial symptom and can be manifested as chronic pelvic pain, dysmenorrhea, dyspareunia, back pain, or dyschezia. Bleeding can be an initial sign and may be manifested as abnormal menstrual bleeding, as rectal bleeding, or if located under the skin, as abdominal ecchymosis. Unfortunately, physical findings in patients with endometriosis are nonspecific and highly related to the location and size of the implants.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The differential diagnosis of pelvic pain in women is quite extensive and includes disease processes in the gastrointestinal, urinary, and reproductive systems (Box 124.2). Careful consideration should always be given to the possibility of acute appendicitis and ovarian torsion in a nonpregnant female with pelvic pain.

**OVARIAN TORSION**

The clinical diagnosis of ovarian torsion is based on findings on physical examination and clinical suspicion, in coordination with pelvic imaging; however, definitive diagnosis is based on surgical findings. Pelvic ultrasound is the first-line diagnostic imaging modality used to aid in identification of ovarian torsion. Doppler ultrasound can be used to identify the physical anatomy of the pelvic organs, as well as to detect ovarian vessel flow. Data on the sensitivity of Doppler ultrasound in detecting ovarian torsion are controversial, especially with regard to vessel flow. Sensitivities as low as 43% and as high as 100% have been reported. In contrast, Doppler ultrasound is quite specific for diagnosing torsion, with sensitivities found to be anywhere from 92% to 97%. It has been reported that up to 50% of patients with torsion may have normal findings on pelvic ultrasound. Therefore, despite negative findings on imaging, if the EP has high enough suspicion for ovarian torsion, prompt gynecologic consultation is warranted. CT and MRI have also been shown to aid in the diagnosis, but their cost and the time required for imaging are prohibitive to regular use of these imaging modalities as long as ultrasound is readily available.

Laboratory testing is generally performed in the setting of acute abdominal pain. Changes in the white blood cell count, hematocrit, and electrolytes have been seen with torsion but are quite nonspecific. Research to identify serum markers is promising, with several studies reporting that increased levels of interleukin-6 are associated with ovarian torsion; however, further investigation is warranted.

**OVARIAN CYSTS**

Routine laboratory studies will generally be ordered in patients with acute abdominal pain, especially with hemodynamic changes, as the physician attempts to rule out a ruptured ectopic pregnancy or acute appendicitis. Laboratory tests
specifically helpful in the setting of hemorrhagic cysts are a hemoglobin level, coagulation profile, and blood type and screen or crossmatch. Again, these tests are nonspecific but aid in monitoring and treatment of patients if they become unstable.

Pelvic ultrasonography is the best imaging modality because it can identify the location and size of a cyst, as well as detect free pelvic fluid, but it is not specific. The physician may also apply the concept of focused assessment with sonography for trauma (FAST) to evaluate for free intraperitoneal fluid, which if positive would raise suspicion for significant hemorrhage. If the diagnosis is unclear after pelvic ultrasound, CT of the abdomen and pelvis may be necessary, especially because it may help evaluate for nongynecologic causes.

**OVARIAN TUMORS**

Many laboratory tests and serum markers can be used to evaluate an ovarian mass; however, much of the work-up is done on an outpatient basis and is guided by a gynecologist. The laboratory testing done by an EP is usually limited to evaluation of pelvic pain in conjunction with vomiting. Further laboratory testing will probably include serum markers such as CA 125, which can be elevated in 80% of women with ovarian malignancy and is 90% sensitive in women with advanced disease. However, given that it has low sensitivity in women with early disease and can be associated with several other gynecologic and nongynecologic illnesses, routine testing in the regular population is discouraged.24,25 Promising studies of human epididymal secretory protein E4 have been shown to be more specific for ovarian carcinoma, but further investigation is warranted.

If the EP suspects or finds an ovarian mass on examination, pelvic ultrasound should be performed. Several characteristics of ovarian tumors should raise the EP’s suspicion for malignancy, such as having a complex internal structure, including complex cysts with solid components; masses in prepubescent or postmenopausal women; or persistence beyond the length of a normal menstrual cycle.

If the findings on ultrasound are equivocal or limited, further diagnostic imaging could include CT scanning of the abdomen and pelvis or MRI. CT scanning is often helpful to the EP who may be trying to evaluate or rule out other causes of pelvic pain or symptoms of a mass effect in these specific patients.

**ENDOMETRIOSIS**

As noted earlier, the diagnosis of endometriosis is made by direct visualization of the implants by surgical methods such as laparoscopy or laparotomy. Laboratory analysis is rarely conducted by the EP aside from evaluating abdominal pain in an undifferentiated patient. Serum CA 125 has been shown to correlate with endometriosis but is not a sensitive marker because it can be elevated in other gynecologic and nongynecologic disease, most notably ovarian carcinoma.

Transvaginal ultrasound is the initial diagnostic imaging test for endometriosis. The classic finding on ultrasound is an ovarian cyst containing low-level homogeneous internal echoes consistent with old blood that correlates with the chocolate cyst found on laparoscopy. MRI has been reported to be useful in cases that require identification of peripheral implant spread, but it is rarely used for this purpose in the ED setting.

**TREATMENT**

Both acute and chronic pelvic pain can be debilitating, and thus early pain management is essential. In a patient with acute pelvic pain a diligent search for the cause in concert with pain management is the best course of action. Oral and intravenous narcotic medications are often needed in this patient population. Unfortunately, in patients with chronic pelvic pain, acute control of pain may be the only intervention that EPs can offer. Disease-specific diagnostic testing and treatment options are described in the following sections.

**OVARIAN TORSION**

Management of ovarian torsion is emergency operative intervention in an attempt at detorsion of the affected adnexal structures and restoration of blood flow and venous drainage. In the past the adnexal structures were surgically resected; however, recent studies and practice have shown that mechanical detorsion is effective and safe. The most important factor in preservation of ovarian function is early recognition and treatment. Several studies have reported high salvage rates when treatment is initiated within the first 24 hours of the onset of symptoms.20,26

**OVARIAN CYSTS**

The mainstay of treatment in the majority of patients with ovarian cysts is pain control. Cyst ruptures are typically self-limited and treated with pain control and expectant management in an outpatient setting. However, significant rupture and intraperitoneal hemorrhage occasionally occur and cause hemodynamic instability. In these cases, urgent gynecologic evaluation and performance of diagnostic laparoscopy or laparotomy are indicated. An unstable patient may require aggressive fluid resuscitation and, in extreme cases, blood products and more aggressive hemodynamic stabilization with pressors or intubation.

**OVARIAN TUMORS**

When the EP finds a highly suspicious ovarian mass, prompt gynecologic referral or consultation must be arranged so that further diagnostic work-up and possible medical or surgical therapy can be initiated. Symptomatic control of bulk-related or pain-related symptoms can include urinary catheter insertion, disimpaction, or narcotic pain medications.

**ENDOMETRIOSIS**

Although optimal treatment of this chronic disease is unclear, options are focused on three main categories—pelvic pain, infertility, and pelvic mass—and tailored to each specific patient. The EP will primarily focus on the treatment of pelvic pain with NSAIDs and combined estrogen-progestin contraceptives. NSAIDs are thought to control pain, as well as affect prostaglandin production, thus altering growth and secretion of the endometrial implants. In a similar manner, OCPs induce decidualization and atrophy of the endometrial tissue and ectopic implants, which may control the cyclic pain and limit progression of the disease. The EP can initiate this therapeutic regimen in the ED setting, but it should be done with close gynecologic consultation or follow-up.

If a conservative medical approach fails, further treatment with GnRH agonists, danazol, aromatase inhibitors, or
conservative surgery may be indicated. All these treatments are coordinated by a gynecologist on an outpatient or inpatient basis, depending on severity of the symptoms.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Most patients with pelvic pain can also be managed on an outpatient basis with directed therapy and gynecologic follow-up. However, acute gynecologic pain, such as ovarian torsion, necessitates admission to the gynecologic service for definitive management.

**TIPS AND TRICKS**

Assume that all women of childbearing age are pregnant until proved otherwise.

In patients with strong suspicion for ovarian torsion despite negative ultrasound findings, prompt gynecologic evaluation is warranted.

About 20% to 25% of cases of endometrial cancer occur before menopause; any patient without a definitive cause of the vaginal bleeding should be referred to a gynecologist for endometrial evaluation.

**DOCUMENTATION**

Age of the patient
Gravid and parous status
Bedside pregnancy test results
Onset and duration of symptoms
Recent trauma
Duration and frequency of past menstrual cycles
Complete sexual history, including contraception methods, number of partners, history of sexually transmitted diseases
History of previous abnormal Papanicolaou smears
Associated symptoms, including fever, breast changes, anorexia, weight changes, hirsutism, bowel or bladder changes
Past medical history
Current medications

Complications of Gynecologic Procedures, Abortion, and Assisted Reproductive Technology

Christine Yang-Kauh

Complications with the highest morbidity and mortality are severe hemorrhage, serious infection, damage to intraabdominal structures, and pulmonary embolism.

Complications seen in the emergency department are usually delayed in presentation, and often difficult to diagnose due to insidious onset, resulting in increased morbidity and mortality and a higher risk for litigation (i.e., ureteral injuries). High suspicion must be maintained.

Emergency department bedside ultrasonography can provide rapid, early imaging for the evaluation of postprocedural patients, particularly unstable ones.

Abortion is one of the most common procedures in the United States and overall has very low serious complication rates.

Ovarian hyperstimulation syndrome is a potentially fatal complication of assisted reproduction in a generally healthy young woman. With no cure, early recognition, aggressive intervention, and close monitoring are key.

This chapter is divided into three main sections—complications of gynecologic procedures, complications following medical and surgical abortion, and complications of assisted reproductive technology (ART).

Gynecologic procedures run the gamut from minor office procedures to major invasive surgery. They can be diagnostic or therapeutic and may initiate pregnancy or terminate it. They represent some of the most common surgical procedures performed in the United States today.

More than 146,000 cycles of ART were reported to the Centers for Disease Control and Prevention from 441 sites in the year 2009. In addition, approximately 600,000 hysterectomies are performed annually, which ranks it behind cesarean section as the most common major surgery in women of reproductive age.

Shortened hospital stays and minimally invasive or outpatient surgery have led to the delayed diagnosis of complications in the emergency department rather than during the postoperative hospitalization period.

COMPLICATIONS OF GYNECOLOGIC PROCEDURES

This section focuses on complications particular to gynecologic procedures that one might encounter in the ED setting and their evaluation and management (Fig. 125.1). Many complications of gynecologic procedures may go unrecognized before discharge, only to be seen later in the ED (Box 125.1). Box 125.2 lists the typical timing of these complications.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

During the evaluation of postoperative patients it is essential to avoid narrowing the differential diagnosis to postoperative complications alone. Other conditions, particularly preexisting ones that may have served as the original indication for surgery (e.g., malignancy, anemia) must be taken into consideration. Laboratory testing and imaging studies should be guided by the differential diagnoses under consideration (see the Priority Actions box).

For patients with complications after a gynecologic procedure, bedside ultrasonography (US) in the hands of a skillful operator can provide rapid recognition of intraabdominal and intrapelvic pathology. Possible ultrasonographic findings include free fluid heralding leakage from a perforated vessel, urinary tract, or viscus (Fig. 125.2); hydronephrosis as a result of ureteral obstruction; a full bladder secondary to urinary retention; fluid collections; and intrauterine contents. US can also be used to guide paracentesis for definitive fluid diagnosis or for the drainage of subcutaneous abscesses. It is important to remember that sensitivity and accuracy are very dependent on the user and interpreter and that anatomy, habitus, and elements such as bowel gas can greatly interfere with adequate imaging. US is a poor modality for evaluating the bowel or retroperitoneal space.

CHAPTER 125  COMPLICATIONS OF GYNECOLOGIC PROCEDURES, ABORTION, AND ART

BOX 125.1 Most Threatening and Most Common Complications of Gynecologic Procedures

Most Threatening
- Vascular injury—consider both intraperitoneal and retroperitoneal
- Bowel injury
- Urinary tract injury—bladder more likely than ureteral
- Sepsis, severe infection
- Pulmonary embolism

Most Common
- Pain
- Bleeding
- Fever
- Wound concerns
- Nausea and vomiting

When a patient with postprocedural complications is seen in the ED, the physician who performed the procedure should be contacted; definitive management often requires gynecologic or other surgical intervention.

URINARY TRACT INJURY

The incidence of urinary tract injury in gynecologic surgery is between 0.33% and 4.8%. The great majority (80%) of these injuries involve the bladder. Ureteral injuries occur in just 0.3% to 1.0% of cases, but unilateral injury is discovered postoperatively in the majority of cases. This delayed recognition leads to increased morbidity. As a result, ureteral injury has become the leading cause of legal action against gynecologic surgeons.

Typical symptoms are fever, flank pain, prolonged ileus, and prolonged abdominal distention. Unexplained hematuria or watery vaginal discharge may be present as well. The most common causes of these symptoms are cystitis and pyelonephritis secondary to perioperative bladder catheterization.

Inability to urinate may represent anuria or urinary retention, which are differentiated by postvoid urinary catheterization or US. No output at all indicates anuria as a result of bilateral compromise or renal failure. Urine residual volume greater than 500 mL suggests urinary retention instead. Bedside US can also detect intraabdominal fluid or hydronephrosis.

Laboratory testing includes a complete blood count and differential, electrolytes, kidney function tests, preoperative blood assays, urinalysis, and urine culture. If ascites or other fluid is obtained, fluid creatinine levels should be measured to determine whether it is urinary in origin. Imaging to evaluate the urinary system is indicated, such as intravenous urography, abdominal/pelvic computed tomography with contrast enhancement, or renal US with retrograde ureteropyelography.

Complications of ureteral obstruction (secondary to ligation, stricture, or external compression by another structure) include hydronephrosis and progressive kidney damage, which ultimately leads to failure of the ipsilateral kidney if...
CHAPTER 125 \ WINTER: CLINICAL MANAGEMENT OF THE WOMAN WITH UROLOGIC COMPLICTIONS

Differential Diagnosis: Complications of Gynecologic Procedures

Abnormal Symptoms or Vital Signs?
Anemia, bleeding
- Hemorrhage may be internal or exsanguinating; emergency resuscitation and exploratory laparotomy are required if unstable. Bedside US for detection of free intraabdominal fluid. For emergency transfusion, use O-negative blood in women with childbearing potential; otherwise, use O positive blood.

Fever
- Consider septic shock, toxic shock syndrome, and necrotizing fasciitis; administer broad-spectrum antibiotics and search for the source of infection. Emergency surgical débridement is required for necrotizing fasciitis.

Abdominal distention
- Consider bowel obstruction or injury to the vasculature, bowel, or urinary tract; bedside US to evaluate for free fluid; upright chest and abdominal radiographs; antibiotics; abdominal/pelvic CT with contrast enhancement if stable; and early surgical evaluation.

Shortness of breath
- Consider pulmonary embolism, fluid overload, and aspiration pneumonia.
- If occurring after laparoscopy, also consider pneumothorax.

Vaginal Bleeding—Is It Cervical or Uterine in Origin?
Cervical or vaginal lacerations: Controlled by simple measures in the ED?
- If yes, discharge with close follow-up with gynecology.
- If not or if after conization, pack and gynecology consultation for management in the operating suite.

Uterine bleeding: Is retained tissue or hemometra noted on ultrasound imaging?
- If yes, gynecology consultation for definitive care.
- If not, consider uterine perforation, and if uterine perforation is present, maintain high suspicion for a perforated viscus and obtain abdominal/pelvic CT. Consider other specific evaluation of nearby structures (i.e., cystoscopy).

Abdominal Pain with Distention?
- Ileus or small bowel obstruction on radiography? Nasogastric tube if excessive vomiting; surgical consultation required.
- If not, consider intestinal, urinary, or vascular injury. Abdominal/pelvic CT imaging.

Unable to Urinate?
Postvoid catheterization or bedside US:
- >500 mL of urine noted? Maintain the urinary catheter and check for a UTI. Substitute a leg bag and treat the UTI if present; discharge to follow-up with urology.
- <200 mL, consider renal failure from medications or bilateral ureteral obstruction. Renal function tests, US to evaluate for hydronephrosis or free fluid. Admit for further evaluation.

Dysuria?
- Hematuria and abdominal pain? Persistent or recurrent UTI? Suspect urinary tract injury; obtain imaging to evaluate for ureteral or bladder compromise.
- If not, treat the UTI with antibiotics, urine culture, and close follow-up.

Wound Redness and Drainage?
Localized? If so, check the fascia; if it is intact, treat as a superficial wound infection with packing and close follow-up. If the fascia is not intact, consider a subfascial abscess, early necrotizing fasciitis, or hernia or evisceration; make sure that it is not an incarcerated hernia; gynecology consultation and possible surgical evaluation are required.

Widespread? Consider cellulitis or fasciitis; administer antibiotics and hospitalize the patient. If only mild cellulitis is present, oral antibiotics, very close follow-up, and explicit return instructions are required (consider priming with first dose of intravenous antibiotics).

CT, Computed tomography; ED, emergency department; US, ultrasound; UTI, urinary tract infection.

Treatment

Antibiotics covering urinary and gastrointestinal pathogens should be initiated early. Gynecology and urology services should be consulted for definitive repair once the diagnosis is made. Ureteral injury can be repaired urgently on the day of diagnosis, or if the patient is unstable, percutaneous nephrostomy can be performed to decompress the kidney while awaiting surgical repair.

If urinary tract injury is ruled out and the diagnosis is simple infection, the patient can be discharged with oral antibiotics.

Vaginal Bleeding

Bleeding from the vagina must be evaluated in the context of the procedure performed. A careful history and speculum examination are key to determining the source, quantity, and persistence of the bleeding.

Blood flowing from the cervical os implies a uterine cause. It may be a result of hemometra (intrauterine hematoma), retained tissue, retained foreign bodies, infection, or uterine...
injury. Bimanual examination helps ascertain the size and tenderness of the uterus. A pelvic US scan must be performed to assess the uterine contents. It can be done at the bedside if the patient is unstable. An acute abdominal radiographic series (flat and upright abdominal views with an upright chest radiograph) to look for signs of perforation may be obtained, but it must be kept in mind that residual pneumoperitoneum from laparotomy or laparoscopy often persists for at least 24 hours and may be present for up to 72 hours.

Uterine perforation is manifested as pelvic cramping and vaginal bleeding. It is of serious concern because of risk for associated injury to adjacent bowel, pelvic vessels, bladder, or other structures. Rapid bedside US by the emergency physician (EP) can be useful to assess for free pelvic fluid suggesting hemorrhage or bladder leakage.

Symptoms of acute hemometra include severe, progressive, cramping pelvic pain. Vaginal bleeding may be minimal if the os is obstructed by the enlarging hematoma. The total blood loss is usually insufficient to cause hypotension or anemia. An extremely distended and tender uterus on bimanual pelvic examination is diagnostic, and bedside US can be used to further support the diagnosis.

In rare cases of persistent bleeding without explanation, an unrecognized bleeding diathesis must be considered. von Willebrand disease is the most common bleeding disorder in women of childbearing age.

### TREATMENT

Minor vaginal or cervical lacerations can be managed in the ED with direct pressure followed by the application of Monsel solution or silver nitrate. Persistent bleeding despite these measures may require sutures or electrosurgery. Bleeding following cold knife conization is often profuse and frequently requires surgical management.

Minor cases of uterine perforation in which the damage was inflicted by a small blunt instrument (e.g., dilator) may be managed conservatively with close observation and consideration of antibiotics if the bleeding is minimal and the patient is otherwise stable. All cases of perforation with a sharp instrument—or significant damage with a blunt instrument—require definitive management with laparoscopy or laparotomy to evaluate the extent of the damage and to stop the bleeding. Cystoscopy may also be necessary if the bladder lies in the path of the perforation. Broad-spectrum antibiotic coverage is indicated.

Definitive treatment of an intrauterine hematoma is suction evacuation of the uterus. This provides prompt relief and can typically be performed without anesthesia or cervical dilation. Afterward, methylergonovine maleate (0.2 mg intramuscularly [IM]) should be administered to induce uterine contraction unless contraindicated by hypertension, in which case a 1000-mcg rectal suppository of misoprostol can be given instead.
ENDOMETRITIS

Patients with endometritis are typically initially seen 3 to 7 days after instrumentation with fever and pelvic or lower abdominal pain and tenderness. Vaginal bleeding is frequently present. Potential pathogens are those of pelvic inflammatory disease, in addition to organisms that may have been introduced during the procedure. Risk factors include retained tissue, as well as pelvic inflammatory disease and insufficiently aseptic operating conditions.

Evaluation consists of pelvic US to assess for retained products and laboratory tests, including a complete blood count and assay for the β subunit of human chorionic gonadotropin (β-hCG).

TREATMENT

Mild endometritis without retained products can be managed on an outpatient basis. Many antibiotic regimens can be used, including a single shot of ceftriaxone, 250 mg IM, plus doxycycline, 100 mg orally twice per day for 14 days, or amoxicillin-clavulanate, 875 mg twice daily, along with the doxycycline. Anaerobic coverage such as metronidazole, 500 mg every 8 hours, may be required as well.

For severe endometritis, inpatient admission is necessary for intravenous (IV) administration of clindamycin, 900 mg every 8 hours, and gentamicin, 1.5 mg/kg every 8 hours. Alternatives are triple IV therapy consisting of ampicillin, 2 g every 6 hours, plus gentamicin, 1.5 mg/kg every 8 hours, and metronidazole, 500 mg every 6 hours, or IV ampicillin-sulbactam, 3.0 g every 8 hours as monotherapy. Doxycycline, 100 mg twice per day for 14 days, should be added if Chlamydia is a possible pathogen.

WOUND AND ABDOMINAL WALL INFECTIONS

Superficial wound infections occur in up to 10% of patients who have undergone gynecologic surgery without perioperative antibiotics. The most common causes are Staphylococcus aureus and vaginal or enteric flora. The great majority of these infections are minor, although systemic toxicity or extensive infection may occur if the initial infection is neglected or in patients who are immunosuppressed, have diabetes, or are obese.

Thorough evaluation requires opening the wound for drainage and examination for deep fascial or muscular involvement. Superficial wound infections can be managed without antibiotics by meticulous wound care, irrigation with diluted hydrogen peroxide or Dakin solution four times per day, and dry gauze packing. Delayed wound closure can be performed if necessary. Table 125.2 details the clinical findings, evaluation, and treatment of wound infections, dehiscence, and necrotizing fasciitis.

VAGINAL EVISCERATION

Vaginal evisceration (bowel and organs protruding from the vagina) is rare, yet dramatic and has a mortality of up to 10% because of associated intestinal necrosis, peritonitis, or other underlying or global illness. It occurs as a result of increased intraperitoneal pressure in the setting of a ruptured vaginal enterocele or unrecognized uterine perforation. The diagnosis is based on findings on physical examination.

TREATMENT

A moist covering must be placed immediately to protect the viscera. Bed rest in the supine or Trendelenburg position is recommended to prevent further outward pressure. Broad-spectrum antibiotics should be administered, and gynecology consultation should be obtained immediately for surgical repair.

COMPLICATIONS SPECIFIC TO LAPAROSCOPY

Laparoscopic procedures are characterized by more rapid recovery and lower complication rates than seen with open surgical procedures. However, unique complications are associated with needle or trocar insertion, induced pneumoperitoneum, and extensive use of electrocautery (Box 125.3). Most catastrophic complications are recognized intraoperatively. Management in the ED in the first month postoperatively is usually for wound complaints or symptoms caused by injury to the bowel, bladder, or ureters. Remote complications include hernias.

BLEEDING

Abdominal wall hematomas may occur as a result of damage to superficial vessels at laparoscopic sites. If the injury is extensive or if the size cannot be estimated because of habitus, a complete blood count can be obtained to estimate and track the blood loss, although the blood lost is not usually sufficient to require transfusion.

Injury to the inferior epigastric vessels can cause intraperitoneal and retroperitoneal bleeding. Patients with slow retroperitoneal bleeding may possibly be seen in the ED if the postoperative observation time was short. Bedside US is of limited utility for evaluating the retroperitoneal space. Worsening flank or back pain soon after the procedure must raise concern for retroperitoneal bleeding. Work-up includes laboratory tests to evaluate for anemia and computed tomography with intravenous contrast enhancement to identify the bleeding.

**Table 125.2 Wound and Abdominal Wall Infections—cont’d**
TREATMENT
Treatment depends on the site and degree of bleeding. The EP should be prepared for blood transfusion and involve the gynecologic surgeon early.

BOWEL INJURY
The incidence of bowel injury from laparoscopic surgery is estimated to be 0.06% to 0.5%, with higher rates for therapeutic procedures than for diagnostic ones, and about 50% to 70% of the time it is diagnosed postoperatively. Most of these bowel injuries are caused by the initial needle insertion or thermal injury with electrocautery. Major injuries are typically discovered intraoperatively because of excessive bleeding or spillage of intestinal contents, but some are less obvious.

Thermal bowel injuries are serious and typically manifested days or even weeks after laparoscopy. Symptoms include abdominal distention, severe lower abdominal pain and tenderness, and fever, often accompanied by nausea, vomiting, and peritoneal signs. Blood tests reveal leukocytosis. Abdominal radiographs may show free air or ileus. Although residual induced pneumoperitoneum may persist for up to 72 hours, in a symptomatic patient the EP should not assume that the free air is benign if it persists longer than 24 hours after laparoscopy.

TREATMENT
Early gynecology consultation should be obtained if thermal injury is suspected. The EP should also consider early empiric antibiotics effective against gastrointestinal pathogens if perforation is suspected or confirmed.

COMPLICATIONS OF UTERINE FIBROID EMBOLIZATION
Uterine fibroid embolization is typically performed by an interventional radiologist to treat bleeding fibroids in patients who are poor candidates for major surgery, are not interested in reproduction, or wish to preserve their menses for personal or for ethnic or religious reasons. The procedure consists of the injection of a mass of microspheres (tris-acryl gelatin) or polyvinyl alcohol directly into the uterine artery to occlude it. The goal is to cut off the blood supply to the fibroids so that they will shrink and degenerate.

A relatively new procedure, uterine fibroid embolization has been rapidly gaining in popularity in the United States, from 50 cases performed in 1996 to now more than 100,000 worldwide. Early results show a success rate of about 90% and a complication rate of about 5% by American College of Gynecology criteria. Patients have a shorter hospitalization and return to activities sooner but have a higher rate of treatment failure and delayed rehospitalization than patients undergoing surgery.

Postembolization syndrome (low-grade fever, malaise, pelvic pain, nausea, and vomiting) affects most of these patients to some degree. Only symptomatic treatment is warranted as long as other causes have been ruled out.

These patients are at risk for angiographic complications such as femoral hematoma, site infection, pseudoaneurysm, arteriovenous fistula, thromboembolism, and contrast agent–induced nephropathy.

Occasionally, the embolization goes awry (“nontarget embolization”), and severe tissue ischemia and necrosis occur in undesirable areas such as the buttock, labia, and vaginal vault. Box 125.4 lists the most common and most life-threatening complications.

TREATMENT
Severe pain from degenerating fibroids can be treated with nonsteroidal antiinflammatory drugs and oral opioids (e.g., acetaminophen with hydrocodone). Infected necrotic tissue or intractable pain may require hysterectomy. Severe bleeding or a sloughed fibroid that is not spontaneously expelled vaginally requires evacuation.

BLEEDING AFTER CERVICAL PROCEDURES
Cervical cancer used to be the top cancer killer of women in the United States. Even though numbers have declined over the past few decades because of the emphasis on regular Papanicolaou tests, in 2007 cervical cancer was diagnosed in 12,280 women, and 4021 died of the disease. Cervical procedures such as cervical conization (laser conization, cold knife conization, loop electrosurgical excision), colposcopy, and cryotherapy are used for the diagnosis and treatment of early cervical neoplasia.

Cold knife conization (surgical excision with a scalpel) is always performed in the operating room, usually with general or spinal anesthesia. Because intraoperative and postprocedural bleeding can be profuse, cerclage is often performed prophylactically before the procedure as a tourniquet. Postconization bleeding is usually manifested 1 to 2 weeks after the procedure.

Laser conization has only slightly lower rates of bleeding. Cervical cryotherapy and loop electrosurgical excision cause just minor bleeding and thus are performed in the outpatient setting.

TREATMENT
Vaginal packing may be attempted, but the patient often needs to return to the operating room for control of hemorrhage.
POSTABORTION COMPLICATIONS

EPIDEMIOLOGY

Since becoming legalized nationwide in 1973, termination of pregnancy has become among the most frequently performed operative procedures in the United States, with more than 1 million performed yearly. A total of 1.2 million cases were reported in 2008. An estimated half of all pregnancies are unplanned, and 40% of unintended pregnancies are terminated. In fact, each year approximately 3% of all women of childbearing age have abortions, thus accounting for almost one fourth of all pregnancies. Most abortions are performed during the first trimester—62% within the first 8 weeks and 95% within the first 16 weeks. Overall complication rates are low, ranging from 1% to 5% of cases, and associated maternal mortality is extremely rare. Death is infrequent, with seven occurring after the almost 1 million legal abortions reported in the United States in 2005. In fact, for every gestational age, mortality is lower with abortion than with pregnancy and childbirth.

Medical abortion has a success rate of 80% to 97% (higher for gestations <50 days); 2% to 5% of patients with failed abortions require subsequent surgical abortion, with a 5% to 10% rate of incomplete evacuation of products of conception.

PATHOPHYSIOLOGY

MEDICAL ABORTION

The three most commonly used abortion medications are mifepristone (an antiprogestin), misoprostol (a prostaglandin), both of which trigger uterine contraction, and methotrexate, an antimetabolite that interrupts embryonic development. Methotrexate and misoprostol are also teratogenic. Thus once used, termination must be completed, even if surgical means are ultimately necessary.

Medical abortion of both live and deceased fetuses between 13 and 28 weeks of gestation is uncommon but can be achieved with prostaglandin E₂ suppositories, carboprost tromethamine, misoprostol, or high-dose oxytocin (80% to 90% effective).

SURGICAL ABORTION

Dilation plus curettage is the most frequently used abortion method in the United States (>90% of abortions). The cervix is dilated and the uterine contents scraped out with a curette or aspirated via vacuum extraction. In the first trimester the overall risk profile is very low (0.1% to 0.3%) and even lower with regional anesthesia. However, the complication rate does increase with increasing gestational age.

Dilation plus evacuation is performed to terminate pregnancies more than 16 weeks of gestation. Dilation is achieved via osmotic dilators (i.e., laminaria) or vaginally administered prostaglandins, as opposed to instrumentation, and the uterine contents are removed with forceps or vacuum. This technique is also used for the management of spontaneous abortion, retained products of conception, intrauterine fetal demise, and gestational trophoblastic neoplasia. Its application
depends on uterine volume, age of gestation, and operator experience.13

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Abortion is a commonly performed procedure and, when performed under medical supervision, rarely has severe complications. The vast majority of terminations are procedural (including vacuum aspiration, sharp curettage, and dilation and evacuation). Medical abortion can be used earlier in the pregnancy and avoids the risks and stigma of procedural termination, but it has a higher incidence of incomplete abortion and failed termination and can be accompanied by severe side effects of the medication and physical discomfort.

General complications of abortion include retained pregnancy, hemorrhage, infection, and incomplete evacuation (Table 125.3); the most threatening and most common complications of abortion are listed in Box 125.5.

In the long term there is a risk for decreased fertility and amenorrhea. Postabortion infection seems to be the only predictor of decreased fertility. For instance, the risk for ectopic pregnancy increases only in cases of postabortal infection. Because ovulation can resume as early as 2 weeks after abortion, contraception should be initiated soon after abortion.

**COMPPLICATIONS OF MEDICAL ABORTION**

The most feared complication is uterine rupture with intraabdominal expulsion of the fetus, especially in women with a scarred uterus (e.g., from a previous cesarean delivery), grand multiparity, and nulliparity with an insufficiently ripened cervix. Common side effects include nausea, vomiting, diarrhea, headache, dizziness, back pain, and fatigue, but it is the severe cramping and heavy bleeding that occur with medical induction that are most likely to bring patients to the ED. Treatment is symptomatic, and regardless of whether the
bleeding is heavy, transfusions are rarely required. It is important to distinguish the natural course of medical termination from incomplete abortion or uterine rupture.

**COMPLICATIONS OF SURGICAL ABORTION**

Surgical abortion carries the risks associated with anesthesia, in addition to those related to the procedure. Complications categorized as immediate, delayed, and long term are listed in Box 125.6.

Complications include uterine perforation, cervical laceration, hemorrhage, incomplete removal of the fetus and placenta, and infection. Very rarely, curettage performed in advanced pregnancy results in a severe, fatal consumptive coagulopathy.

The most common postprocedural complaints are bleeding and pain. Uterine bleeding may be due to retained products of conception, uterine atony, infection, uterine arteriovenous malformation, placenta accreta, coagulopathy (secondary to high levels of tissue thromboplastin released during the procedure), or uterine perforation.

**HEMORRHAGE**

Posttermination vaginal bleeding in the natural course of abortion must be differentiated from pathologic causes. Determination of the abortion method, rate of bleeding, and accompanying symptoms such as fever, abdominal pain, and symptoms of acute anemia is essential.

Diagnostic testing includes a complete blood count, coagulation studies, basic metabolic profile, type and screen (or crossmatch if the bleeding is brisk and uncontrolled), and US to evaluate for intrauterine contents. Bedside US revealing free fluid or an upright chest radiograph revealing free air is sufficient evidence of perforation and the need for emergency exploratory laparotomy. Heavy bleeding or a nonfundal perforation requires evaluation of the adjacent intraabdominal organs for collateral damage. In a stable patient, US is required to evaluate the pelvic structures, followed by a computed tomography scan if the US image is equivocal. Incomplete abortion is one of the most common causes of ongoing bleeding, and US is extremely useful for making the diagnosis.

Uterine atony is a diagnosis of exclusion and can be treated medically after the findings on US and hemoglobin levels are within normal limits.

Uterine perforation carries a high risk for concomitant damage to the intraperitoneal structures and severe hemorrhage. Delayed manifestation is not uncommon because fundal perforations (accounting for two thirds of all perforations) have scant bleeding. Lateral perforations may have heavy bleeding hidden in the broad ligament, and a lacerated uterine artery may initially spasm. The signs and symptoms depend on the site of perforation (Table 125.4). Uterine perforation related to surgical abortion or uterine rupture from medical abortion must be considered in patients with vaginal bleeding and abdominal pain.

**TREATMENT**

The EP must first establish that the patient is stable, resuscitate if necessary, and then determine whether the source of bleeding is vaginal, cervical, or uterine. Resuscitation of unstable patients is paramount. Management includes rapid diagnosis, large-bore IV access, fluid resuscitation or transfusion (or both), and gynecologic consultation.

Uterine perforation related to surgical abortion and uterine rupture from medical abortion are surgical emergencies, so gynecology must be involved early. Laparotomy or laparoscopy to examine the abdominal contents is usually indicated, although small perforations may be managed expectantly with consideration of antibiotic treatment. In the presence of rapid bleeding, insertion of a Foley catheter into the uterus and inflation of the balloon with 60 mL of saline can serve as a temporizing tamponade (Table 125.5).

Definitive treatment of incomplete abortion with retained products of conception is dilatation and curettage. Gynecology should be consulted and antibiotics should be considered because retained products place patients at risk for infection.
Lacerations of the vagina or cervix are treated with direct pressure, followed by the application of Monsel solution or silver nitrate if needed.

Treatment options for uterine atony are methylergonovine maleate (Methergine), 0.2 mg IM, carbetoprost tromethamine (Hemabate), 250 mcg IM every 15 to 90 minutes with a maximum total dose of 2 mg, misoprostol, 1000-mcg suppository per rectum, or oxytocin (Pitocin), 40 units in 1 L of 5% dextrose in NS by IV drip, with the drip rate titrated to control bleeding.

Heavy ongoing hemorrhage without an obvious source and with symptomatic or profound anemia requires temporizing packing and exploration in the operating room or uterine artery embolization.

**POSTABORTION INFECTION**

Postabortion infection is infrequent, but when it does occur, it is usually a result of retained products of conception or unrecognized preexisting infection.

Patients with endometritis usually have fever, prolonged vaginal bleeding, and pelvic pain. A midline boggy mass may be noted on examination. Laboratory tests include a complete blood count, coagulation profile, β-hCG level, and cervical cultures. Transvaginal pelvic US should be performed to evaluate for retained tissue.

Though extremely rare and seen mostly following illegal abortions, severe and fatal infections are possible. Other major complications include severe hemorrhage, septic shock, disseminated intravascular coagulation, and acute renal failure. Uterine infection is most common, but parametritis, endocarditis, peritonitis, and septicemia may occur and are typically due to anaerobic coliforms.

Diffuse abdominal tenderness with guarding, fever, tachycardia, and hypotension suggests severe sepsis. Laboratory tests should include a complete blood count with differential, electrolytes, kidney and liver function, coagulation profile, lactate studies, β-hCG, a blood bank sample, urinalysis, and cervical and urine cultures.

**TREATMENT**

Postabortion infections require antibiotics, as well as suction curettage. The antibiotic regimens recommended are usually based on guidelines of the Centers for Disease Control and Prevention for treating pelvic inflammatory disease and include IV clindamycin, 900 mg every 8 hours, plus gentamicin, 1.5 mg/kg every 8 hours; triple coverage with ampicillin, gentamicin, and metronidazole is indicated for sicker patients; and ampicillin-sulbactam is used as monotherapy in less severe cases. Treatment of sepsis begins with rapid stabilization and aggressive IV fluid resuscitation. Broad-spectrum intravenous antimicrobials and gynecology consultation for definitive evacuation of the products of conception should not be delayed.

IM, Intramuscularly; IV, intravenous; NS, normal saline.
Despite the growing frequency of ART, however, published data on complications are limited. What does exist focuses primarily on outcomes of the pregnancy (multiple-birth gestations, low-birth-weight babies, cesarean sections, and preterm delivery), as well as long-term effects on women and the resultant children. These complications are dealt with only indirectly in the ED.

### PATHOPHYSIOLOGY

The subfertility of a couple can be attributed to male factor, female factor, or incompatibility issues. Male factor infertility includes dysfunctional sperm, inadequate sperm concentration, and obstruction. Female factor infertility can be due to ovulatory dysfunction, poor egg quality, anatomic abnormalities, or hormonal imbalance. Compatibility factors include a hostile environment.

Many techniques are used in the course of assisted reproduction, and rapid advances have been made over the last 2 decades. ART incorporates techniques of controlled ovarian hyperstimulation, egg or sperm retrieval, insemination, and embryo transfer. Selection of the ART methods used depends on the specific fertility issues identified. During the course of evaluation and preparation, each party may undergo diagnostic and corrective procedures before the initiation of assisted reproduction.

The five basic stages of ART for women are ovulation (natural or induced), egg harvesting, implantation of the egg and sperm or fertilized zygote, pregnancy, and delivery. Each stage has its own risks. For men, the risks are limited mostly to procedures for the acquisition of sperm.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

When dealing with these patients, the EP must keep in mind that infertility specialists are typically very involved in the management of their patients and would prefer to have close communications regarding the patient’s status while being able to provide close monitoring and follow-up.

Major complications of ART likely to be encountered in the ED include ovarian hyperstimulation syndrome (OHSS), ectopic or heterotopic pregnancy, miscarriage, ovarian torsion, ovarian rupture, thromboembolism, and postprocedural complications (Table 125.6 and Box 125.7).

*Major complication.

ART, Assisted reproductive technology; EVLBW, extremely very low birth weight; FSH/LH, follicle-stimulating hormone/medical hormone; GnRH, gonadotropin-releasing hormone; hMG, human menopausal gonadotropin; LBW, low birth weight; OHSS, ovarian hyperstimulation syndrome; PROM, premature rupture of membrane; VLBW, very low birth weight.
Transvaginal US–guided oocyte aspiration is typically an ambulatory procedure involving intravenous analgesia and sedation. Risks include vascular injury with bleeding from the vaginal puncture site, hemoperitoneum, rupture of ovarian cysts, bowel perforation, injury to pelvic organs, and infection.

Bleeding from the vaginal mucosa because of the harvesting punctures typically resolves spontaneously by the end of the procedure or with direct pressure. Topical hemostatic agents may be used if compression fails. Persistent or significant bleeding despite these measures requires suturing.

Intraabdominal bleeding should be suspected in patients with postprocedural symptoms of anemia even before peritoneal signs become evident.

If vital signs remain stable and the patient is minimally symptomatic, conservative management is possible; however, hemodynamic instability unresponsive to basic fluid resuscitation or a falling hemoglobin level in a symptomatic patient requires emergency exploratory laparotomy for definitive diagnosis and correction. Typed and crossmatched blood should be used for transfusion if the patient is sufficiently stable. Uncrossmatched O-negative blood can be used for immediate transfusion if necessary.

**EMBRYO TRANSFER**

Pelvic infection, ectopic or heterotopic pregnancy, spontaneous expulsion of the embryo, and multiple-gestation pregnancy may complicate embryo transfer.

**ECTOPIC AND HETEROTOPIC PREGNANCIES**

Despite careful placement of embryos in the uterus, approximately 4% of in vitro fertilization pregnancies are ectopic. This incidence is slightly reduced with US guidance of embryo placement; however, migration of the embryo may occur occasionally. Ectopic pregnancies as a result of ART are usually diagnosed very early because of close monitoring by the fertility specialist.

Heterotopic pregnancies (multigestational pregnancies with at least one ectopic and one intrauterine pregnancy) are very rare with spontaneous conception (1 in 30,000) but occur in up to 1% of assisted conception cycles. This number is expected to decrease as technology continues to improve and the use of single-embryo transfer increases. In patients with symptoms consistent with a possible ectopic pregnancy, the presence of an intrauterine pregnancy does not rule out a heterotopic ectopic pregnancy, and a full work-up should be performed.

Management of patients who have undergone the psychological, physical, and financial burden of using ART and have a heterotopic pregnancy should be focused on maintaining the intrauterine pregnancy while eliminating the ectopic pregnancy and avoiding excessive risk to the mother.

**MULTIPLE-GESTATION PREGNANCIES**

In 2009, 31% of infants born as a result of ART were multiple-gestation births, in contrast to approximately 3% of births in the general population.11

Multiple embryos are often placed in the uterus because of the low implantation rate per embryo (10% to 25%). Although this can be welcome news to the expectant parents, these multifetal pregnancies are associated with an increased risk for mortality and morbidity in both the mother and fetuses.
Maternal complications include preterm labor, placental abruption and placenta previa, cesarean section, postpartum hemorrhage, gestational diabetes, and preeclampsia. Fetuses are at risk for the secondary effects of maternal complications, as well as prematurity, low birth weight, intrapartum demise, and congenital conditions such as cerebral palsy. As new technologic developments increase the success of implantation, however, protocols are changing to dictate the transfer of only one or two embryos.

**OVARIAN HYPERSTIMULATION SYNDROME**

**Epidemiology**

OHSS is the most feared complication of ovulatory stimulation. Severe OHSS is life-threatening and occurs in an estimated 0.5% to 5% of ART cycles. It also occurs occasionally in spontaneous pregnancy. The estimated mortality rate is 1 in 400,000 to 500,000 patients.15

**Pathophysiology**

OHSS is characterized by increased capillary permeability with third spacing of protein-rich fluid. This results in hemoconcentration with severe intravascular hypovolemia manifested as edema, ascites, and pleural and pericardial effusions. Multisystem organ failure, renal failure, immunosuppression, pulmonary failure, thromboembolism, and death may result.

Through an unclear mechanism, hCG appears to be a trigger for OHSS. The syndrome is usually manifested within a week of exogenous hCG administration and oocyte retrieval and has a second peak of incidence after implantation as a result of the rise in endogenous hCG.

Risk factors include young age, low body mass index, use of gonadotropin-releasing hormone analogues and exogenous hCG, elevated estradiol levels, increased number of stimulated follicles during controlled ovarian hyperstimulation (“necklace sign” or “string of pearls” appearance on US images), polycystic ovarian disease, and previous OHSS (Box 125.8).

**Presenting Signs and Symptoms**

Patients have abdominal pain and distention, nausea, and vomiting and may complain of constipation or diarrhea. Chest discomfort, dyspnea, concentrated oliguria, rapid weight gain, and peripheral edema are symptoms of more severe cases.

Physical examination reveals abdominal distention with tenderness in the bilateral lower quadrants and tender, enlarged ovaries. Increasing evidence of third spacing such as peripheral edema, ascites, dull lung fields consistent with pleural effusion, and distant heart sounds are evident in patients with severe disease.

**Differential Diagnosis and Medical Decision Making**

Laboratory testing reveals serum estradiol levels elevated to higher than 3000 pg/mL, hemoconcentration with hyponatremia and hyperkalemia, and decreased renal function. Pelvic US with Doppler is essential to evaluate for the presence of ascites (Fig. 125.3) and the extent of follicular recruitment (Fig. 125.4) while ruling out alternative diagnoses such as ovarian torsion.

**Treatment**

No specific cure is available for OHSS; treatment is empiric and focused on supportive care until spontaneous resolution occurs (Table 125.7). The syndrome is usually self-limited.

Early detection and prevention are key. Individuals at risk should receive only low-dose gonadotropins and be monitored closely by the fertility specialist. The development of symptoms, elevated estradiol levels (>3000 pg/mL), or excessive follicular recruitment (>20) calls for the initiation of preventive treatment strategies such as decreasing hormone dosages, freezing the embryos rather than waiting for fresh embryo transfer, administering albumin during oocyte harvesting, and

**Fig. 125.3** Ascites and pleural effusion in a patient with ovarian hyperstimulation syndrome.

**Fig. 125.4** Polycystic ovarian syndrome affecting both ovaries in a patient with ovarian hyperstimulation syndrome.
“coasting” (withholding further gonadotropin administration until estradiol levels decrease, which allows fresh embryo retrieval and transfer). In extreme circumstances, the stimulation protocol should be terminated.

MILD CASES Mild cases can be managed on an outpatient basis with very close follow-up and daily monitoring of weight, abdominal girth, and urine output. Conservative management focuses on treating pain and maintaining hydration, although some treatment strategies include high-protein diets and high-sodium drinks (e.g., exercise rehydration drinks). Progressive symptoms or weight gain of more than 2 lb should prompt hospital admission. In the absence of pregnancy, the symptoms are expected to resolve about 2 weeks after hCG was administered.

MODERATE CASES Patients with moderate disease require a complete work-up, including laboratory tests and US, and hospitalization is recommended for close observation and serial examinations, as well as for symptomatic care if the patient has disabling nausea, intractable abdominal pain, tense ascites, abnormal laboratory values, or other indications of a downward trajectory. Pelvic examination is not recommended in moderate or severe cases because of the risk for cyst rupture with hemorrhage. There should be a low threshold for admission to the hospital for monitoring, but typically these patients are being very closely followed by their fertility specialist; if the symptoms are controlled adequately, the patient can be discharged to follow-up in the next 1 to 3 days. She should be instructed to maintain a record of fluid balance and avoid physical activity.

SEVERE CASES Severe OHSS requires inpatient care in the intensive care unit. Strict monitoring of fluid balance and hemodynamics is critical. Large-bore IV access must be established for fluid resuscitation, and a subclavian line for central venous pressure is advised.

Aggressive repletion of the intravascular space starts with at least 2 to 3 L of normal saline. If urine output remains inadequate (<50 mL/hr), salt-poor IV albumin (or hydroxyethyl starch) is the next step. Lactated Ringer solution should be avoided because of elevated potassium levels.

Ongoing oliguria and renal failure in the face of aggressive volume repletion may be due to abdominal compartment syndrome with elevated intraperitoneal pressure compressing the renal vasculature. This can be relieved with therapeutic paracentesis. Bedside US guidance is recommended to avoid puncturing the enlarged ovaries.

Diuretics are not suggested as first-line care because they may deplete the intravascular space and increase the risk for Table 125.7 Management of Patients with Ovarian Hyperstimulation Syndrome

thromboembolism; however, once hemodilution has been achieved, following each 100 mg of albumin with 10 to 20 mg of furosemide may be of benefit in patients with recalcitrant prerenal azotemia.

Prophylaxis for deep vein thrombosis is essential given the high risk for thromboembolic disease.

Syndrome-associated hypoglobulinemia results in a relative immunosuppression. Antibiotic choice should target specific suspected infectious causes.

**Complications of Assisted Reproductive Technologies**

**Induction Phase**

Abdominal pain, distention or ascites? Initiate a work-up and symptomatic treatment of OHSS. Obtain a US scan and estradiol levels.

Difficulty breathing and unstable? If signs of third spacing are present, suspect severe OHSS; start aggressive symptomatic and supportive treatment. Admit to the ICU.

Dyspnea with only leg edema or without any evidence of third spacing? Consider PE; obtain a chest radiograph. Anticoagulation and lower extremity vascular Doppler US are required to evaluate for DVT. If still equivocal, obtain a helical CT scan of the chest with IV contrast enhancement.

Pelvic pain? Consider early OHSS.

**Any Time During ART**

Pelvic pain? Perform Doppler US to evaluate for ovarian torsion versus ovarian cyst rupture.

**After Oocyte Harvesting**

Fever? Consider infection; administer antibiotics and evaluate whether stable for discharge.

Vaginal bleeding from a puncture site? Place pressure. If the bleeding does not stop, consider Monsel solution or silver nitrate.

Abdominal pain or peritoneal signs? Consider intraperitoneal hemorrhage; cardiovascular stabilization and definitive exploratory laparotomy are required.

**After Implantation or Embryo Transfer**

Pelvic pain or vaginal bleeding? Perform or obtain a pelvic US and check quantitative β-hCG to evaluate for ectopic or heterotopic pregnancy or threatened spontaneous miscarriage.

**PATIENT TEACHING TIPS**

**Ovarian Hyperstimulation Syndrome**

Clarify the details of the anticipated therapeutic course. Schedule follow-up with the patient’s physician in 1 to 3 days.

Instruct her to call her physician or return to the emergency department immediately if progressive symptoms of ovarian hyperstimulation syndrome develop, including:

- Chest discomfort
- Difficulty breathing
- Abdominal pain
- Bloating and swelling, rapid weight gain
- Decreased urination
- Severe or persistent vomiting

Warn the patient that there can be a second peak in symptoms after implantation triggered by her own hormonal surge.

**RED FLAGS**

**Complications of Assisted Reproductive Technology**

Increased abdominal girth, abdominal pain, edema, and dyspnea during induction of ovulation or early after implantation are suspicious for ovarian hyperstimulation syndrome.

Unilateral pelvic pain is suspicious for ectopic pregnancy or ovarian torsion.

Severe pain, fever, brisk bleeding, and peritoneal signs are suspicious for perforation.

Shortness of breath, possibly with pleuritic chest pain, should prompt evaluation for pulmonary embolism, although pleural effusions as a result of ovarian hyperstimulation syndrome are also possible.

Selection of medication must take into careful consideration the possible existence of early pregnancy.

**CRITICAL CASES**

Critical cases with complications such as renal failure, thromboembolism, or acute respiratory distress syndrome require all of the previously described measures and termination of the pregnancy.

**REFERENCES**

References can be found on Expert Consult @ www.expertconsult.com.
REFERENCES

Not all gynecologic infections, including pelvic inflammatory disease, are sexually transmitted, although many are. They are often asymptomatic in women and their sex partners.

Sexually transmitted diseases are common, particularly in young, sexually active women with multiple sex partners.

A careful history, physical examination, and diagnostic tests are important to differentiate gynecologic infections because modalities of treatments vary.

Microscopic diagnosis of yeast infections has a sensitivity of only 50% and fails to diagnosis the disorder in a large percentage of patients with symptomatic vulvovaginal candidiasis.

Most young, sexually active patients with genital ulcers have a genital herpes infection; syphilis or chancroid disease should be considered as well.

Treatment should be instituted for most gynecologic infections based on the presumed diagnosis because many patients with genital infections will not have a laboratory-confirmed diagnosis.

Gonorrhea is becoming increasingly resistant to antibiotics; the clinician should check local susceptibilities before treatment.

Genital ulcers may also be caused by chancroid, granuloma inguinale, herpes simplex virus (HSV), lymphogranuloma venereum (LGV), and syphilis.

CHANCROID

EPIDEMIOLOGY

The number of reported cases of chancroid in the United States has varied for the past 10 years but remains very low. Only 28 cases were reported domestically in 2009.1

PATHOPHYSIOLOGY

Chancroid, a sexually transmitted disease caused by the short gram-negative bacillus Haemophilus ducreyi, is characterized by painful genital ulcers and painful lymphadenopathy.2 The incubation period is 4 to 7 days.

H. ducreyi infection occurs through loss of integrity of the epithelial layer of the skin, most commonly following minor trauma such as sexual intercourse. Once the bacteria have breached the integument, secretion of a cytologically lethal toxin causes apoptosis and necrosis of cells, which results in the characteristic ulcer formation seen with chancroid.

PRESENTING SIGNS AND SYMPTOMS

H. ducreyi forms a vesicopustule that progresses to a painful ulcer with a necrotic base and surrounding erythema. Because of autoinoculation, multiple lesions may develop.
PATHOPHYSIOLOGY

Granuloma inguinale is a chronic granulomatous anogenital infection caused by *Calymmatobacterium granulomatis*. Granuloma inguinale is primarily a sexually transmitted disease, but gastrointestinal transmission is possible. Its onset is insidious, with a median incubation period of about 50 days.

PRESENTING SIGNS AND SYMPTOMS

The lesions, which can occur on the skin and mucous membranes of the genitalia or perineal area, are relatively painless nodules that transform into shallow, sharply demarcated ulcers with a red base. The lesions spread by contiguity, and the ulcer then becomes purulent, painful, and foul smelling.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

C. granulomatis is difficult to culture because it is an intracellular parasite. Identification is usually made from scraped material or a biopsy specimen obtained from the periphery of the lesion. Bipolar-staining bacteria are best identified within mononuclear cells (Donovan bodies) by Wright or Giemsa staining. Note that genital ulcers are also caused by syphilis, chancroid, and LGV.

TREATMENT

Several treatment regimens have been recommended and are listed in Box 126.1.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Follow-up within 1 week to reevaluate the ulceration is recommended. Safe sex practices, such as condom use, as well as regular genital self-examination, should be discussed. Sexual partners should be informed.

GRANULOMA INGUINALE (DONOVANOSIS)

Epidemiology

The incidence of granuloma inguinale is low, with less than 100 cases reported in the United States per year. The peak demographic of occurrence is in people between the ages of 20 and 40 years who are sexually active.

begin with painful lesions that are often described as burning (Fig. 126.1). These lesions begin as vesicles and then rupture to expose an ulcerated base that persists for 1 to 2 weeks before crusting over and healing without scars. The vesicles and ulcers contain many highly infectious virus particles, and viral shedding occurs until the lesions disappear. Vulvar lesions may last for 3 or more weeks before complete healing. The cervix and vagina may also be involved, with a gray, necrotic cervix and profuse leukorrhea. External dysuria is common, and bilateral inguinal lymphadenopathy is usual.

The primary episode, defined as genital herpes without antibodies to HSV-1 and HSV-2, is typically associated with systemic symptoms, including headache, fever, malaise, and other flulike symptoms in about two thirds of the cases. Following primary infection, latent HSV usually localizes in the sacral ganglion and perhaps the dermis. Recurrent attacks tend to be more subtle and are the most frequently seen outbreaks in the emergency department (ED). Recurrence can be precipitated by immunodeficiency, trauma, fever, or sexual intercourse.

A significant number of patients with the typical signs and symptoms of herpesvirus infection are later found to have syphilis; therefore, screening for treponemal antibodies is an important part of the ED evaluation. The diagnosis of HSV infection can be made clinically if the typical, painful, shallow multiple vulvar ulcers are present. Laboratory confirmation is best attained by polymerase chain reaction (PCR) testing.

**HERPES SIMPLEX VIRUS**

**EPIDEMIOLOGY**

HSV is widespread in the United States, with approximately 50 million people infected, and it is the most common cause of genital ulcers. The overall domestic seroprevalence of subtype 2 (HSV-2) is 16.2%, but infection rates are considerably higher (39.2%) in African Americans. HSV-2 is the most common variant causing genital infections, but subtype 1 (HSV-1) is the causative agent in up to 10% to 15% of all cases.

**PATHOPHYSIOLOGY**

Two types of HSV may cause genital herpes: HSV-1 and HSV-2. Once acquired, genital herpes becomes a lifelong infection. Herpes simplex is a DNA virus with an incubation period ranging from 2 to 7 days. Transmission occurs through exposure to infectious secretions of mucosal surfaces or through skin microabrasions during sexual contact.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

A significant number of patients with the typical signs and symptoms of herpesvirus infection are later found to have syphilis; therefore, screening for treponemal antibodies is an important part of the ED evaluation. The diagnosis of HSV infection can be made clinically if the typical, painful, shallow multiple vulvar ulcers are present. Laboratory confirmation is best attained by polymerase chain reaction (PCR) testing.
**LYMPHOGRANULOMA VENEREUM**

**EPIDEMIOLOGY**

LGV is rarely reported in developed countries—perhaps in part because of the lack of a standardized diagnostic test or surveillance requirements. However, outbreaks have been reported in populations of homosexual men in Western Europe and North America since 2003, with the largest cluster of case reports occurring in the United Kingdom and New York City.5

**PATHOPHYSIOLOGY**

LGV is an acute or chronic sexually transmitted disease caused by *Chlamydia trachomatis* types L1, L2, and L3. The disease is acquired during intercourse or through contact with contaminated exudates from active lesions. *C. trachomatis* enters the system through loss of skin integrity (breaks and abrasions) or by crossing the epithelial cells of mucous membranes and multiplies in regional lymph nodes after lymphatic dissemination. The primary mode of transmission is sexual; however, spread by fomites, nonsexual personal contact, and laboratory accidents has been documented.

**PRESENTING SIGNS AND SYMPTOMS**

The most common clinical manifestation of LGV in heterosexuals is tender inguinal or femoral lymphadenopathy (or both), which is typically unilateral. The initial vesicular or ulcerative lesion is transient and often goes unnoticed. Inguinal buboes appear 1 to 4 weeks after exposure and have a tendency to fuse, soften, and break down to form multiple draining sinuses with extensive scarring. In women, genital lymph drainage is to the perirectal glands. Early anorectal manifestations include proctitis with tenesmus and bloody purulent discharge; late manifestations are chronic inflammation of rectal and perirectal tissue. These changes can lead to obstruction, rectal stricture, and occasionally, rectovaginal and perianal fistulas.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The early lesion of LGV must be differentiated from the lesions of syphilis, genital herpes simplex, chancroid, and granuloma inguinale; lymph node involvement must be distinguished from that caused by tularemia, tuberculosis, plague, neoplasm, or pyogenic infection; and rectal stricture must be distinguished from that secondary to neoplasm and ulcerative colitis.

The complement fixation test may be positive, but cross-reaction with other chlamydiae occurs. Although a positive reaction may reflect remote infection, high titers usually indicate active disease. Specific immunofluorescence tests for immunoglobulin M are more specific for acute infection.

---

**BOX 126.3 Treatment Regimens for Herpes Simplex Virus**

A. **Initial infection** (first episode): Recommended regimens for initial infection should be given orally for 7 to 10 days (may be extended if healing is incomplete).
   - Acyclovir, 400 mg three times per day or 200 mg five times per day
   - Famciclovir, 250 mg three times per day
   - Valacyclovir, 1 g twice per day

B. **Recurrent infection** (episodic treatment): Recommended regimens are given orally.
   - Acyclovir, 400 mg three times per day for 5 days, 800 mg twice per day for 5 days, or 800 mg three times per day for 2 days
   - Famciclovir, 125 mg twice per day for 5 days, 1 g twice per day for 1 day, or 500 mg once followed by 250 mg twice daily for 1 day
   - Valacyclovir, 500 mg twice per day for 3 days or 1 g once per day for 5 days

C. **Suppressive therapy**: Given for frequent recurrent infections and includes several recommended oral regimens.
   - Acyclovir, 400 mg twice per day
   - Famciclovir, 250 mg twice daily
   - Valacyclovir, 1 g once per day

**TREATMENT**

Treatment of HSV infection is dependent on the onset of clinical symptoms (acute versus recurrent) and their frequency, which determines the need for suppressive therapy (Box 126.3).

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Timely outpatient referral to gynecology should be made. Patients should be informed of the potential for recurrent episodes, as well as the potential for transmission of HSV even when symptoms are not present. Sexual activity should be avoided when active genital lesions or prodromal symptoms are present. In pregnant patients, immediate referral to obstetrics for potential cesarean section to avoid transmission of the virus from mother to fetus should be made if rupture of membranes has occurred. HSV serves as a cofactor in the transmission of HIV.
arthralgia, pharyngitis, and lymphadenopathy. This stage is typically seen 4 to 10 weeks after the initial appearance of a chancre. Infectivity can occur in the first two stages (up to 2 to 4 years following infection).

The third stage—the asymptomatic latent phase—may last many years. It is defined as syphilis characterized by seroreactivity without other evidence of disease.

The fourth stage—tertiary syphilis—has numerous neurologic, cardiovascular, and other systemic effects and develops in about 25% of untreated patients.6

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The diagnosis of syphilis should be considered in any patient with an ulcerative lesion in the genital area, as well as in patients with unexplained rashes, arthralgia, and neurologic or systemic complaints.

Screening includes the rapid plasma reagin and Venereal Disease Research Laboratory tests, which must be followed by confirmatory testing when positive. If the serologic results are nonreactive and spirochetes cannot be demonstrated by darkfield examination, the serologic tests should be repeated in 1 month.

**TREATMENT**

Penicillin remains the mainstay of treatment across the board (Box 126.5). According to the CDC guidelines, parenteral penicillin is considered to be the only treatment documented to be efficacious in pregnancy.3 Treatment with penicillin is the same as for the corresponding stage of syphilis in non-pregnant women. For pregnant patients who are allergic to penicillin, tetracycline and doxycycline are contraindicated. Pregnant patients who are allergic to penicillin should be skin-tested and desensitized.

---

**BOX 126.4 Treatment Regimens for Lymphogranuloma Venereum**

A. **Recommended regimen**: It is the preferred treatment.
- Doxycycline, 100 mg orally twice per day for 21 days*

B. **Alternative regimen**: Recommended regimens are given orally.
- Erythromycin, 500 mg four times per day for 21 days

*Doxycycline is contraindicated in pregnant women.

---

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Appropriate treatment should resolve all symptoms and result in no significant sequelae. Patients should be advised to notify sexual contacts to be evaluated for possible infection. Complications of LGV include cervicitis, perimetritis, salpingitis, fistula development, and rectal stricture.

---

**SYphilis**

**EPIDEMIOLOGY**

Rates in women increased from 0.8 case per 100,000 in 2004 to 1.4 cases per 100,000 in 2009 despite a previously decreasing incidence.1

**PATHOPHYSIOLOGY**

Syphilis is a systemic, sexually transmitted disease caused by the spirochete *Treponema pallidum*. It can also be acquired congenitally. The risk for transmission following sexual exposure depends on many factors and is estimated to be about 30%. T. pallidum causes infection after traversing mucous membrane surfaces or denuded skin and then extending systematically through hematogenous and lymphatic routes.

**PRESENTING SIGNS AND SYMPTOMS**

Syphilis can be seen in the ED in any of the four stages through which untreated syphilis can pass. Primary infection is manifested as a single, painless ulcer, usually within 3 weeks but sometimes 2 to 3 months after infection. The labia and vaginal walls are most often affected; however, lesions can also occur on the cervix (Fig. 126.2). Secondary syphilis is associated with a characteristic maculopapular generalized rash on the palms and soles and may include components of arthralgia, pharyngitis, and lymphadenopathy. This stage is typically seen 4 to 10 weeks after the initial appearance of a chancre. Infectivity can occur in the first two stages (up to 2 to 4 years following infection).

The third stage—the asymptomatic latent phase—may last many years. It is defined as syphilis characterized by seroreactivity without other evidence of disease.

The fourth stage—tertiary syphilis—has numerous neurologic, cardiovascular, and other systemic effects and develops in about 25% of untreated patients.6

---

**Fig. 126.2** Primary syphilis with a chancre in the vagina. The lesions are painless and may never be detected.
### BOX 126.5 Treatment Regimens for Syphilis

**A. Primary and secondary infections:**
- Benzathine penicillin G, 2.4 million units intramuscularly (IM)
- For penicillin-allergic nonpregnant patients:
  - Doxycycline, 100 mg orally twice daily for 14 days 
  - Tetracycline, 500 mg orally four times daily for 14 days
- For children and infants:
  - Benzathine penicillin G, 50,000 U/kg IM up to the adult dose of 2.4 million units

**B. Latent syphilis:**
- Benzathine penicillin G, 7.2 million units total administered as 3 doses of 2.4 million units IM each at 1-week intervals
- For penicillin-allergic nonpregnant patients:
  - Doxycycline, 100 mg orally twice daily for 28 days
  - Tetracycline, 500 mg orally four times daily for 28 days
- For children and infants:
  - Benzathine penicillin G, 50,000 U/kg IM up to the adult dose of 2.4 million units administered as 3 doses at 1-week intervals (total of 150,000 U/kg up to the adult total dose of 7.2 million units)

**C. Tertiary syphilis** (with no evidence of neurosyphilis): For example, patients with gumma and cardiovascular syphilis.
- Benzathine penicillin G, 7.2 million units total administered as 3 doses of 2.4 million units IM each at 1-week intervals
- Consult infectious disease specialists for penicillin-allergic patients

**D. Neurosyphilis:**
- Recommended regimen: Aqueous crystalline penicillin G, 18 to 24 million U/day administered as 3 to 4 million units intravenously (IV) every 4 hours or as a continuous infusion for 10 to 14 days
- Alternative regimen: Procaine penicillin, 2.4 million units IM once daily, plus probenecid, 500 mg orally four times per day, both for 10 to 14 days
- Limited data suggest that ceftriaxone, 2 g daily either IM or IV for 10 to 14 days, may be effective for patients with neurosyphilis

The Jarisch-Herxheimer reaction, caused by massive release of treponemal antigens and manifested by fever, headache, and myalgias, can occur in any patient in the first 24 hours following initiation of therapy and is observed most often in patients with early syphilis (frequently in those with secondary syphilis). Because this reaction in pregnant women may precipitate early labor or cause fetal distress, these patients should be hospitalized for monitoring. Concern for this reaction should not prevent or delay therapy. Systemic glucocorticoids administered 12 hours before or concurrent with antibiotics may minimize the effects, and antipyretics have been used for supportive care.

### FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Quantitative serologic tests should be performed in patients with syphilis to monitor the results of treatment. Sexual contacts must be notified and evaluated for possible infection. All patients with syphilis should be tested for HIV to assess for possible coinfection. Delay in diagnosis during pregnancy past 20 weeks’ gestation should prompt fetal ultrasound to rule out congenital syphilis.

### BACTERIAL VAGINOSIS

#### EPIDEMIOLOGY

Although the range is wide, depending on the population, prevalence rates for bacterial vaginosis (BV) have been estimated to be 4% to 40%. However, because *Gardnerella vaginalis* is present in 50% to 70% of asymptomatic women, the exact incidence of BV is difficult to estimate.

#### PATHOPHYSIOLOGY

BV is a polymicrobial infection that results from replacement of the normal *Lactobacillus* species in the vagina by high concentrations of the anaerobic *G. vaginalis*, *Mycoplasma hominis*, and *Mobiluncus curtisi*. It can be a precursor infection to upper genital tract extension, including cervicitis and pelvic inflammatory disease (PID). Infection is related to the *Lactobacillus* concentration and changes in pH within the vaginal vault but remains primarily multifactorial.

#### PRESENTING SIGNS AND SYMPTOMS

Clinical signs include a thick, homogeneous, milky vaginal discharge sometimes with a fishy odor. Usually, no other symptoms are present.

#### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

BV can be diagnosed with the use of clinical criteria (see Amsel’s diagnostic criteria below) or Gram stain, with the
latter considered to be the “gold standard” laboratory method for diagnosis. Clinical diagnosis requires three of the following four criteria:

- Homogeneous, thin vaginal fluid that adheres to the vaginal walls
- Presence of vaginal epithelial cells with borders obscured by adherent small bacteria (clue cells)
- Vaginal fluid pH higher than 4.5
- Release of an amine “fishy” odor with alkalinization (adding 10% KOH) of the vaginal fluid (“whiff test”)

### TREATMENT

Only women with symptoms require treatment (Box 126.6).

### FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Recurrence rates for BV have not been shown to be affected by treatment of males; therefore, sex partners do not need to be referred for evaluation. Follow-up is recommended only if symptoms persist after treatment.

### TRICHOMONIASIS

#### EPIDEMIOLOGY

Trichomoniasis affects 2 to 3 million women in the United States per year. A total of 216,000 visits to physician offices were reported in women 15 to 44 years of age for this issue in 2009 alone.¹

<tr>
<td>• Clindamycin ovules, 100 mg intravaginally once at bedtime for 3 days</td>
</tr>
</tbody>
</table>

### PATHOPHYSIOLOGY

Trichomoniasis is caused by *Trichomonas vaginalis*, an anaerobic protozoan that is transmitted primarily through sexual activity. *T. vaginalis* measures 10 µm in diameter and structurally has a flagellum that allows it to move around vaginal and urethral tissues. The incubation period for infection ranges from 4 to 28 days.

### PRESENTING SIGNS AND SYMPTOMS

Many women infected with *T. vaginalis* are asymptomatic. Typical symptoms, if present, include vulvar irritation, dyspareunia, dysuria, urinary frequency, and a malodorous, profuse, purulent vaginal discharge. Physical examination may reveal an erythematous vaginal mucosa or punctate hemorrhages on the cervix.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Although candidiasis and BV are included in the differential diagnosis of vaginitis, trichomonal infections are less typically associated with pruritus or malodor.¹ The diagnosis is made by identification of motile trichomonads on a saline wet preparation but are seen in only 60% to 70% of confirmed cases when cultures are performed.

### TREATMENT

Treatment regimens are listed in Box 126.7. Patients with allergy to a nitroimidazole may undergo metronidazole desensitization. Because of adverse pregnancy outcomes with *Trichomonas* infection, such as premature rupture of membranes, preterm delivery, and low birth weight, women can be treated with 2 g metronidazole in a single dose at any stage of pregnancy.

### BOX 126.7 Treatment Regimens for Trichomoniasis

<tbody>
<tr>
<td>• Metronidazole, 500 mg orally twice per day for 7 days</td>
</tr>
</tbody>
</table>

Patients in whom trichomoniasis is diagnosed should be advised to notify sex partners to seek treatment because of the known exposure. Investigation for persistent trichomoniasis versus an alternative diagnosis such as candidiasis or gonorrhoea should be pursued on follow-up via repeated examination if vaginal discharge is still present.

**VULVOVAGINAL CANDIDIASIS**

Vulvovaginal candidiasis (VVC) is exceedingly common, with 75% of women expected to have at least one episode during their lifetime. However, only 10% to 20% of women will have symptoms to the extent that diagnostic and therapeutic considerations are warranted.

**PATHOPHYSIOLOGY**

*Candida albicans* is a normal vaginal flora that is the primary cause of 25% of cases of vaginitis and approximately 90% of vaginal yeast infections (noncandidal species cause the remaining infections). These saprophytic fungi are isolated from the vagina in 20% to 40% of asymptomatic women. Infection should especially be suspected in women who have recently been taking antibiotics or high-dose estrogen oral contraceptives and in women who are immunosuppressed (e.g., due to diabetes or corticosteroid therapy). The pH of vaginal secretions is maintained by the normal vaginal flora (*lactobacilli, diphtheroids, and Staphylococcus epidermidis*) and should be 4.0 to 4.5. Several factors such as age, phase of the menstrual cycle, hormonal contraception, and sexual activity may change the vaginal milieu by causing an increase in vaginal pH and hence may result in vulvovaginitis.

**PRESENTING SIGNS AND SYMPTOMS**

Common symptoms include vulvovaginal pruritus, dyspareunia, external dysuria, and a white, thick, curdlike vaginal discharge. Physical examination typically reveals erythematous or edematous mucosa in addition to the classic discharge described previously.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Several infections may mimic VVC; however, the diagnosis is based on the characteristic clinical findings along with microscopy. Microscopic evaluation reveals a normal pH (4 to 4.5) with hyphae, pseudohyphae, or budding yeast on a saline wet preparation or 10% potassium hydroxide preparation. Fifty percent of women with candidiasis have a negative wet mount but a positive *Candida* culture. Recurrent VVC, defined as four or more episodes of symptomatic VVC in 1 year, affects 5% of women. Vaginal cultures should be performed for patients with recurrent VVC to confirm the clinical diagnosis and to identify unusual species (including non-*albicans* species), particularly *Candida glabrata*.

**TREATMENT**

Treatment regimens are listed in Box 126.8. For recurrent VVC caused by *C. albicans*, some specialists recommend a longer duration of initial therapy (e.g., 7 to 14 days of topical therapy or a 100-mg, 150-mg, or 200-mg oral dose of fluconazole every third day for a total of three doses [days 1, 4, and 7]) before initiating a maintenance antifungal regimen. Maintenance regimens include oral fluconazole (i.e., 100-mg, 150-mg, or 200-mg dose) weekly for 6 months, which is the first line of treatment. If this regimen is not feasible, topical treatments used intermittently as a maintenance regimen can be considered. For severe VVC (i.e., extensive vulvar erythema, edema, excoriation, and fissure formation), either 7 to 14 days of topical azole or 150 mg of fluconazole in two

Diseases Characterized by Cervicitis and Urethritis

CHLAMYDIA

EPIDEMIOLOGY

C. trachomatis infection is the most commonly reported notifiable disease in the United States. C. trachomatis and Neisseria gonorrhoeae are isolated in combination in about 20% to 40% of women with purulent cervicitis, but accurate disease rates are limited by the fact that 80% of women infected with these pathogens are asymptomatic. During the period 2005 to 2009, the chlamydial infection rate in women increased by 20.3% (from 492.2 to 592.2 cases per 100,000 females).

PATHOPHYSIOLOGY

C. trachomatis is an obligate intracellular bacterium that is transmitted sexually. Chlamydial infections in women are usually asymptomatic and may lead to PID, which is a major cause of infertility and ectopic pregnancy. Women are most commonly seen with infection of the genital tract, typically 1 to 3 weeks after exposure.

PRESENTING SIGNS AND SYMPTOMS

Chlamydial infection is usually asymptomatic and frequently not identified until overt infection develops. It causes a variety of clinical signs and symptoms, including intermenstrual or postcoital bleeding, lower abdominal pain, and even fever. Chlamydia can cause cervicitis, PID, and Fitz-Hugh–Curtis syndrome (FHCS).

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Chlamydial infections can be diagnosed by culture. However, newer DNA methods using ligase chain reaction or PCR offer both sensitivity and specificity not achieved with the older tests. For DNA tests, samples should be taken from the cervix or from urine.

TREATMENT

Treatment regimens are listed in Box 126.9. In pregnant women, treatment with doxycycline, ofloxacin, and levofloxacin are contraindicated. Therefore, the recommended regimen is azithromycin, 1 g orally in a single dose, or amoxicillin, 500 mg orally three times per day for 7 days, with erythromycins being the alternative regimen.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients in whom VVC is diagnosed should be advised to have their sex partners evaluated as well given that males with symptomatic balanitis should be identified and treated to prevent recurrent female infection. Avoidance of vaginal douching is encouraged to minimize disruption of the normal vaginal milieu.

BOX 126.9 Treatment Regimens for Uncomplicated Genital Chlamydia Infections

Recommended Regimens
- Azithromycin, 1 g orally in a single dose
  or
- Doxycycline, 100 mg orally twice per day for 7 days

Alternative Regimens
- Erythromycin base, 500 mg orally four times per day for 7 days
  or
- Erythromycin ethylsuccinate, 800 mg orally four times per day for 7 days
  or
- Levofloxacin, 500 mg orally once daily for 7 days
  or
- Ofloxacin, 300 mg orally twice per day for 7 days

GONORRHEA

EPIDEMIOLOGY

The highest incidence of infection is found in the 15- to 24-year-old age group, and transmission occurs via sexual contact. In 2009, the gonorrhea rate was 105.5 cases per 100,000 population in women.¹

PATHOPHYSIOLOGY

N. gonorrhoeae, a gram-negative diplococcus typically found inside polymorphonuclear cells, is the causative agent in gonorrhea infections. Incubation times for gonorrhea range from 3 to 5 days. Infection is usually asymptomatic, but if present, the most common clinical sign is endocervicitis. The virulence and pathophysiology of N. gonorrhoeae subtypes depend on the antigenic characteristics of the organism.

PRESENTING SIGNS AND SYMPTOMS

As mentioned in the previous section, infection is often asymptomatic, but if manifestations do develop, they often occur during menses and have a clinical picture similar to that of Chlamydia infection. Patients may have dysuria, urinary frequency, and urgency with a purulent urethral discharge. Vaginitis and cervicitis with inflammation of the Bartholin glands are common findings. Infection may be asymptomatic with only slightly increased vaginal discharge and moderate cervicitis on physical examination. Infection may remain as a chronic cervicitis—an important reservoir of gonococci. Systemic complications follow dissemination of gonococci from the primary site via the bloodstream and include meningitis, endocarditis, and arthritis.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Gonococcal urethritis or cervicitis must be differentiated from nongonococcal urethritis; from cervicitis or vaginitis secondary to C. trachomatis, G. vaginalis, T. vaginalis, or C. albicans; and from many other pathogens associated with sexually transmitted disease. Gram stains are often negative.

In the past, culture has been the gold standard for diagnosis; however, nucleic acid amplification tests that detect both N. gonorrhoeae and C. trachomatis in cervical and urethral swab specimens and urine have become more widely used.

TREATMENT

Therapy is typically administered before antimicrobial susceptibilities are known (Box 126.10). The decision to treat can be based on laboratory confirmation; however, in patients with high clinical suspicion for the disease or in those likely to be lost to follow-up, empiric therapy should not be delayed. Specific antibiotic regimens are recommended for patients with complicated gonococcal infections such as bacteremia, endocarditis, arthritis, meningitis, and conjunctivitis. Because antibiotic resistance is becoming an increasing problem, the physician should check local sensitivities before treating.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients should be advised to notify sex partners to be treated based on exposure regardless of the presence or absence of symptoms. Unprotected sexual intercourse should be avoided until 7 days after completion of the treatment regimen. Uncomplicated cases should be referred to follow-up with a primary care or public health provider within 72 hours for reevaluation. Use of condoms should be recommended with the understanding that they offer partial protection. Serologic testing for syphilis should be performed in all patients with gonorrhea.

URETHRITIS

EPIDEMIOLOGY

Causative agents of nongonococcal urethritis include Ureaplasma urealyticum (40% to 60% of cases), C. trachomatis
(15% to 55% of cases), M. hominis (5% to 10% of cases), and T. vaginalis (<5% of cases). 1

PATHOPHYSIOLOGY

Urethritis can result from infectious and noninfectious conditions. Infectious urethritis is usually transmitted sexually and is categorized as gonococcal urethritis (N. gonorrhoeae) or nongonococcal urethritis (i.e., C. trachomatis, U. urealyticum, M. hominis, Mycoplasma genitalium, T. vaginalis). Asymptomatic infections are common. Rare infectious causes of urethritis most commonly include LGV, herpes genitalis, syphilis, and adenovirus.

PRESENTING SIGNS AND SYMPTOMS

Symptoms, if present, include discharge of mucopurulent or purulent material, dysuria, and urethral pruritus.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Gram stain is the preferred rapid diagnostic test for evaluating urethritis. The presence of gram-negative intracellular diplococci on a urethral smear is indicative of gonorrhea infection, which is frequently accompanied by chlamydial infection. If Gram stain microscopy is not available, patients should be treated with drug regimens effective against both gonorrhea and chlamydia.

Urethritis can be documented on the basis of any of the following signs or laboratory tests:

• Mucopurulent or purulent discharge on examination
• Microscopy of urethral secretions demonstrating five or more white blood cells (WBCs) per oil immersion field
• Positive leukocyte esterase test on first-void urine or microscopic examination of first-void urine sediment demonstrating 10 or more WBCs per high-power field

TREATMENT

For gonococcal urethritis, refer to the treatment of uncomplicated gonorrhea infections. Because of possibility of concomitant infection, Chlamydia infection should be presumed and also treated unless it is ruled out. See Box 126.11 for the treatment of nongonococcal urethritis.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Reevaluation is recommended if the symptoms persist or recur following completion of therapy. Alternative causes (T. vaginalis, HSV, adenovirus, Mycoplasma, and Ureaplasma species) should be pursued when nongonococcal urethritis does not improve with the recommended treatment.

BOX 126.11 Treatment Regimens for Nongonococcal Urethritis

Recommended Regimens
• Azithromycin, 1 g orally in a single dose or
• Doxycycline, 100 mg orally twice per day for 7 days

Alternative Regimens
• Erythromycin base, 500 mg orally four times per day for 7 days or
• Erythromycin ethylsuccinate, 800 mg orally four times per day for 7 days or
• Levofloxacin, 500 mg orally once daily for 7 days or
• Ofloxacin, 300 mg orally twice per day for 7 days

Recurrent or Persistent Urethritis
• Metronidazole, 2 g orally in a single dose or
• Tinidazole, 2 g orally in a single dose, plus azithromycin, 1 g orally in a single dose (if not used for the initial episode)

Diseases Characterized by Abdominal or Pelvic Pain

PELVIC INFLAMMATORY DISEASE

EPIDEMIOLOGY

PID is diagnosed in more than 1 million women each year. 1 Infertility as a result of tubal involvement after PID is the second most common cause of female infertility in the United States. Following PID, infertility occurs in 12% of women; the risk for ectopic pregnancy increases 7- to 10-fold, and chronic pelvic pain develops in approximately 20% of women. 11

PATHOPHYSIOLOGY

PID is a polymicrobial infection of the upper genital tract (endometrium, fallopian tubes, ovaries) that is associated most commonly with N. gonorrhoeae and C. trachomatis and, to a lesser extent, with some endogenous organisms, including anaerobes, Haemophilus influenzae, and enteric gram-negative
rods. Retrograde spread of the organisms occurs in as many as 20% of women with cervicitis and often results in PID with salpingitis, endometritis, or tuboovarian abscesses (TOA). PID is most common in young, nulliparous, sexually active women with multiple sex partners.

The specific mechanism of infection in PID is unknown. However, numerous risk factors have been identified, including previous sexually transmitted disease, high number of sexual partners, inconsistent or no regular use of condoms, sexual intercourse at an early age, and intrauterine devices. Pregnancy can be a protective factor because of the mucous plug, which helps prevent upward transmission of infection.

**PRESENTING SIGNS AND SYMPTOMS**

Symptoms suggesting PID include bilateral lower abdominal pain, dyspareunia, vaginal discharge (75% of patients), abnormal vaginal bleeding, low back pain, nausea and vomiting, and fever. Mucopurulent discharge or leukorrhea in the vaginal vault has good sensitivity but low specificity for PID.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Diagnosis of PID is usually based on the clinical findings of lower abdominal tenderness, cervical motion tenderness, or adnexal tenderness for which another cause is not likely (Box 126.12). Women with PID may have subtle or mild symptoms, thus complicating the diagnosis.

The differential diagnosis includes appendicitis, ectopic pregnancy, septic abortion, hemorrhagic or ruptured ovarian cysts or tumors, degeneration of a myoma, and acute enteritis (Fig. 126.3).

**TREATMENT**

Antimicrobial coverage should include *N. gonorrhoeae*, *C. trachomatis*, gram-negative facultative bacteria, anaerobes, and streptococci. No single therapeutic regimen has been established (Box 126.13). Outpatient management is appropriate for most patients with mild to moderate PID who do not meet the criteria for admission.

As a result of the emergence of quinolone-resistant *N. gonorrhoeae*, regimens that include a quinolone agent are no longer recommended for the treatment of PID. Parenteral therapy may be discontinued 24 hours after the patient improves clinically, and oral therapy with doxycycline, 100 mg orally twice daily, should be continued for a total of 14 days.

**BOX 126.12 CDC Suggested Criteria for Diagnosis, Empiric Treatment, and Hospitalization for Patients with PID**

<table>
<thead>
<tr>
<th>A. Minimum diagnostic criteria (for diagnosis and empiric treatment of PID in sexually active young women experiencing pelvic or lower abdominal pain if no other cause is identified):</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Cervical motion tenderness</td>
</tr>
<tr>
<td>or</td>
</tr>
<tr>
<td>• Adnexal tenderness</td>
</tr>
<tr>
<td>or</td>
</tr>
<tr>
<td>• Uterine tenderness</td>
</tr>
</tbody>
</table>

**B. Additional diagnostic criteria (used to enhance specificity of the diagnosis of PID once any of the minimum criteria listed above is met):**

| • Oral temperature higher than 101°F (>38.3°C) |
| • Abnormal cervical or vaginal mucopurulent discharge |
| • Presence of abundant numbers of WBCs on saline microscopy of vaginal fluid |
| • Elevated erythrocyte sedimentation rate |
| • Elevated C-reactive protein |
| • Laboratory documentation of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis* |

**C. Additional diagnosis criteria (most specific criteria for the diagnosis of PID):**

| • Histopathologic evidence of endometritis on an endometrial biopsy specimen |
| • Transvaginal ultrasonography, computed tomography¹² (see Fig. 126.3), or magnetic resonance imaging showing thickened, fluid-filled tubes with or without free pelvic fluid and a tuboovarian complex |
| • Laparoscopic abnormalities consistent with PID |

**D. Criteria for hospitalization (recommended criteria for hospitalization of patients with PID):**

| • Unable to exclude surgical emergencies such as appendicitis in the diagnosis |
| • Pregnancy |
| • Presence of tuboovarian abscess |
| • Severe illness such as intractable nausea and vomiting, high fever, or leukocytosis |
| • Inability to follow or tolerate an outpatient oral regimen |
| • Failure to respond clinically to oral antimicrobial therapy |

CDC, Centers for Disease Control and Prevention; PID, pelvic inflammatory disease; WBCs, white blood cells.

---

**Fig. 126.3** Computed tomography scan of a patient with pelvic inflammatory disease showing bilateral adnexal masses. A, Tuboovarian abscesses; U, uterus.
**BOX 126.13 Treatment Regimens for Pelvic Inflammatory Disease**

**Outpatient Treatment Regimens**
Recommended regimen:
- Ceftriaxone, 250 mg intramuscularly (IM) once, plus doxycycline, 100 mg orally (PO) twice daily for 14 days, with or without metronidazole, 500 mg PO twice daily for 14 days
  - or
- Cefoxitin, 2 g IM in a single dose, and probenecid, 1 g PO, administered concurrently in a single dose, plus doxycycline, 100 mg PO twice daily for 14 days, with or without metronidazole, 500 mg PO twice daily for 14 days
  - or
- Cefotaxime, 500 mg (or ceftriaxone, 500 mg) IM once, plus doxycycline, 100 mg PO twice daily for 14 days, with or without metronidazole, 500 mg PO twice daily for 14 days

Alternative regimen:
- If parenteral cephalosporin therapy is not available: Fluoroquinolones (levofloxacin, 500 mg PO once daily, or ofloxacin, 400 mg twice daily for 14 days) with or without metronidazole (500 mg PO twice daily for 14 days)

**Inpatient Treatment Regimens (Parenteral)**
Recommended regimen:
- Cefotetan 2, g intravenously (IV) every 12 hours (or cefoxitin, 2 g IV every 6 hours), plus doxycycline, 100 mg PO or IV every 12 hours
  - or
- Clindamycin, 900 mg IV every 8 hours, plus a gentamicin loading dose IV or IM (2 mg/kg of body weight), followed by a maintenance dose (1.5 mg/kg) every 8 hours. Single daily dosing (3 to 5 mg/kg) can be substituted

Alternative regimen:
- Ampicillin-sulbactam, 3 g IV every 6 hours, plus doxycycline, 100 mg PO or IV every 12 hours

---

**TUBOOVARIAN ABSCESS**

**EPIDEMIOLOGY**

TOA is the most common intraabdominal abscess in premenopausal women and develops in up to one third of patients hospitalized with PID. Rupture is categorized as a surgical emergency with rates of occurrence as high as 15%.

**PATHOPHYSIOLOGY**

TOA is usually a complication of PID, although cases can infrequently occur without the preexisting presence of PID. TOAs typically result from salpingitis that progresses to oophoritis. Ovarian infection occurs after contamination with purulent material from the fallopian tube. Adherence of tubal fimbriae to the ovary forms a large, cylinder-shaped TOA. Most TOAs consist of polymicrobial anaerobic bacteria.

**PRESENTING SIGNS AND SYMPTOMS**

Patients with TOA typically have abdominal pain and severe, asymmetric tenderness, often with peritoneal signs on palpation. Fever and leukocytosis are usually but not always present as well. TOA can be bilateral, although unilateral disease is more common and accounts for 60% of such abscesses.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Definitive diagnosis is made by direct visualization or use of an imaging study. Pelvic ultrasonography has a reported sensitivity of 93% and specificity of 98%. Computed tomography may be used to define the abscess better or may be appropriate if the ultrasound evaluation is inconclusive. Appendicitis, PID, and ovarian torsion are common entities in the differential diagnosis.

**TREATMENT**

All patients with suspected TOA should be hospitalized. Initial parenteral therapy options are the same as those listed for PID, but continued oral therapy should include clindamycin (or metronidazole) for 14 days in addition to doxycycline.

TOAs may require transcutaneous or transvaginal aspiration. Surgical excision is also an option. Unless rupture is suspected, high-dose antibiotic therapy should be instituted, and the efficacy of therapy should be monitored with ultrasonography. Ruptured TOA is a life-threatening condition that requires immediate medical therapy associated with surgery.

Unilateral adnexectomy is acceptable for unilateral abscesses. Hysterectomy and bilateral salpingo-oophorectomy may be necessary for overwhelming infection or in cases of chronic disease with intractable pelvic pain.

---

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Compliance with the full 2-week course of oral antibiotic therapy should be encouraged. Advise against sexual activity pending resolution of the disease process. Patients should be referred for follow-up in 72 hours for reevaluation. Patients should be advised to notify any sex partners who were active with the patient during the 60 days before the onset of symptom to receive treatment as per CDC recommendations.
Laparoscopy is useful to identify unclear cases and, in conjunction with positive cervical or abdominal cultures, represents the standard criterion for diagnosis. Negative cervical cultures alone, however, do not rule out the diagnosis. “Violin string” adhesions may be seen on ultrasound or computed tomography scans (Fig. 126.4).

The goal of treatment is bacterial eradication with antibiotics to prevent chronic abdominal pain and adhesions. Complications are uncommon but can include subdiaphragmatic abscess and small bowel obstruction.

Although no formal antibiotic recommendations exist, patients with FHCS usually require admission for observation and parenteral antibiotic therapy. Initial options are the same as those listed for inpatient treatment of PID. Like TOA, continued outpatient oral therapy should include clindamycin (or metronidazole) for 14 days in addition to doxycycline.

Compliance with the full 2-week course of oral antibiotics should be encouraged. Patients should be referred for follow-up in 72 hours for reevaluation. Advise against sexual activity pending resolution of the disease process.
CHAPTER 126 GYNECOLOGIC INFECTIONS

Diseases Characterized by Genital Warts or Mucosal Abscess

HUMAN PAPILLOMAVIRUS

EPIDEMIOLOGY

HPV is the most common sexually transmitted virus in the United States. Its prevalence corresponds inversely with age (highest in younger age groups, 50% in females 20 to 24 years of age) and declines substantially after the age of 24 years. However, the gross clinical prevalence of HPV is less than 1%.

PATHOPHYSIOLOGY

HPV is a double-stranded DNA virus that infects the epithelial cells of skin and mucosa and can cause cellular changes leading to formation of warts. HPV infection is a sexually transmitted illness that is most commonly asymptomatic but has been associated with various disease processes such as benign anogenital warts, as well as with invasive cancer. Of the greater than 100 types of HPV, more than 40 can infect the genital area. A quadrivalent HPV vaccine that provides protection against types 6, 11, 16, and 18 was licensed for use in the United States in June 2006. HPV subtypes 6 and 11 most commonly cause genital warts (condylomata acuminata), which can occur on the vulva, perianal area, urethra, vaginal walls, or cervix. These subtypes have also been identified as the causative agent of laryngeal or respiratory papillomatosis in infants and children, but the route of transmission is not completely understood.

PRESENTING SIGNS AND SYMPTOMS

The average incubation period for visible warts is about 3 months. Genital warts may be asymptomatic but can be pruritic. On clinical examination the lesions are generally papillary, verrucous (wartlike), or macular in character (Fig. 126.5).

Lesions usually first appear individually, but large confluent growths can develop.

Vaginal and cervical warts are more common than labial warts, although most of them are flat lesions visible only with colposcopy.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Several laboratory methods such as PCR have been developed for confirmation of genital HPV infection, but the ED diagnosis remains primarily clinical.

Fig. 126.5 Vulvovaginal human papillomavirus infection. (From Cohen J, Powderly WG. Infectious diseases. 2nd ed. Philadelphia: Mosby; 2004.)

Vulvar warts must be differentiated from the less verrucous, flatter growths of syphilitic condyloma latum and from carcinoma in situ of the vulva. Darkfield examination or punch biopsies may be required to differentiate these lesions.

Vulvar lesions may be obviously wartlike or may be diagnosed with colposcopy following the application of 4% acetic acid (vinegar), after which they appear whitish with prominent papillae.

TREATMENT

Subclinical genital HPV infection usually clears spontaneously. Treatment is indicated for those with genital warts or precancerous lesions and not for subclinical HPV infection (Box 126.14).

Extensive warts may require CO2 laser treatment under local or general anesthesia. Intravesical interferon, photodynamic therapy, and topical cidofovir are associated with more side effects and are no more effective than other therapies.

In women who have exophytic cervical warts, biopsy evaluation to exclude high-grade squamous intraepithelial lesions must be performed before treatment is initiated. Management of exophytic cervical warts should include consultation with a specialist.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Curative measures to prevent transmission once infected are not available, and therefore routine examination of sex
BARTHOLIN GLAND ABSCESS

EPIDEMIOLOGY

Swelling of the Bartholin glands occurs in 2% of women of reproductive age, most commonly between the ages of 20 and 30. Development of this disease process in patients older than 40 years is atypical and should lead to assessment for possible malignancy as part of the diagnostic and treatment plan.

PATHOPHYSIOLOGY

The Bartholin glands are bilateral vulvovaginal secretory structures located in the labia minora on the posterolateral aspect of the vestibule. Normally pea sized, these glands drain fluid through a 2.5-cm duct into a fold between the hymeneal ring and the labium that serves to maintain moisture of the vaginal mucosa. Duct occlusion can result in cyst and subsequently abscess formation. Isolates from cultures of abscesses are most commonly anaerobic organisms (Bacteroides fragilis, Peptostreptococcus), aerobic N. gonorrhoeae is the causative agent in approximately 10% to 15% of cases, and C. trachomatis is found even less frequently.

PRESENTING SIGNS AND SYMPTOMS

Onset of disease can occur rapidly over a period of several hours or may progress more gradually over several days. The initial symptoms are pain, dyspareunia, and sometimes fever. Findings on physical examination are a unilateral labial mass with tenderness, redness, and swelling in the Bartholin gland area. Elevated temperature is observed in approximately one third of patients.

Microscopically, acute inflammation is present within the Bartholin duct, as well as within the gland stroma about the duct. The abscess, when fully developed, contains purulent exudate.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Cultures and Gram staining of material expressed from the duct may identify gonococci. Cervical gonococcal and chlamydial cultures should be performed and the organisms treated if present.

TREATMENT

Management of the abscess consists of simple incision and drainage. After sterile preparation of the area, a scalpel stab incision, ideally no longer than 1.5 cm (longer incisions will make it difficult to keep the Word catheter in place), should be made deep into the abscess from the inside of the labium. An outside incision can cause permanent fistula formation.17 Loculations should be broken manually followed by placement of a Word catheter with its balloon tip inserted into the abscess before inflation with water or lubricating gel (Fig. 126.6). Simple incision and drainage without Word catheter placement may be inadequate and result in recurrence.

After successful drainage, routine antibiotic therapy is not recommended for uncomplicated Bartholin gland abscesses in otherwise healthy women. Treatment of N. gonorrhoeae and C. trachomatis should be initiated only in patients with confirmed disease.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Follow-up in 72 hours for reevaluation should be arranged. Refer the patient to gynecology for removal of the catheter in 2 to 4 weeks.

Breast Disorders
Robert Lockwood and Jamie L. Collings

KEY POINTS

• There are very few true breast emergencies, and immediately life-threatening causes such as traumatic breast rupture or necrotizing fasciitis are exceedingly rare.
• Breast pain, particularly if cyclic, is common, and benign causes predominate.
• Breast cancer is a possible diagnosis in any patient with a chief complaint related to the breast, including breast pain or a mass, nipple discharge, or skin lesions.
• Most patients in whom breast cancer is diagnosed have no risk factors except age older than 50 years and female sex, and eight of nine patients have no family history of breast cancer.
• The emergency physician can play a role in reduction of the risk for lymphedema by early and aggressive treatment of even very minor infections and burns.
• Most medications are safe for use while breastfeeding, and the benefits of continuing breastfeeding generally outweigh the potential for harm.
• Few maternal infections, other than human immunodeficiency virus, present a significant risk to the breastfeeding infant.

EPIDEMIOLOGY

Approximately one half of visits to physicians for breast complaints are for pain. New, palpable masses represent another common breast-related complaint. Although a benign condition will be diagnosed in 9 of 10 premenopausal women with a palpable breast mass, a new mass in a 75-year-old woman is malignant up to 70% of the time. Breast cancer is the most common cause of cancer-related mortality in women worldwide and second only to lung cancer in women in the United States. In 2006, it accounted for one third of all cancer diagnoses in women in the United States.¹

Although there are few true breast-related emergencies, perioperative issues represent a second significant group of emergency department (ED) visits. Breast surgery is relatively common in the United States. In addition to the 90,000 mastectomies performed annually, approximately 100,000 cosmetic augmentations and 100,000 reduction mammoplasties take place each year.² Many patients undergoing breast augmentation, either for reconstruction or cosmesis, experience significant complications and require additional surgery.

PATHOPHYSIOLOGY

The unique anatomic structure of the breast contributes to the wide variety of pathologic conditions that may occur. Each breast contains approximately 20 glandular units (lobes) composed of glands and adipose tissue (Fig. 127.1). Each lobe drains into a lactiferous duct, which fuses with other ducts to form lactiferous sinuses just below the skin. The lactiferous sinuses store milk during lactation. Disruption (obstruction, infection, inflammation) of the glandular system may occur at any time during a female's lifetime but predominates between menarche and menopause. The breast's diffuse vascular network predisposes it to hematogenous spread of malignancy, as well as infection.

Virtually all breast conditions that occur in women are seen in men as well, including benign conditions such as fat necrosis, allergic and irritant dermatitis, mastitis and abscesses, and mammary tuberculosis. Malignant entities such as adenocarcinoma of the breast, Paget disease of the nipple, and lymphoma occur less frequently in men than in women. Breast cancer in men accounts for less than 1% of the total number of breast malignancies diagnosed in the United States. However, in other areas in the world (e.g., central Africa), male breast cancer is significantly more common. Men are at higher risk for the development of malignant melanoma and basal cell carcinoma of the breast. One condition, gynecomastia, occurs exclusively in men.

PRESENTING SIGNS AND SYMPTOMS

Similar to other sensitive or visible areas, ED visits for breast complaints are often precipitated by a change in appearance of the tissue. Discoloration, erythema, and engorgement are some of the more notable changes that may occur. It is very important to determine the context within which these changes are taking place. Patients with breast pain while lactating are clearly quite different from those whose pain is a result of an automobile accident. Patients can typically be segregated into

Acknowledgment and thanks to Dr. Karen Jubanyik for her contribution to the first edition.
Breast Disorders

MASTALGIA

Breast pain, especially as an isolated symptom, can be thought of as originating from one of three broad categories: cyclic mastalgia, noncyclic mastalgia, or extramammary.

Cyclic mastalgia occurs in premenopausal women, is associated with worsening symptoms in the late luteal phase of the menstrual cycle, and accounts for two thirds of patients with mastalgia. The typical pain of cyclic mastalgia is “achy” or “heavy” and bilateral. Resolution with the onset of menses is very reassuring.

Findings on physical examination may be normal, or tender nodularities may be detected. Fibrocystic breast conditions (the term fibrocystic breast disease has been replaced by the term fibrocystic breast condition to emphasize that it represents a spectrum of histologic entities) are not associated with axillary lymphadenopathy, skin thickening, edema or discoloration, or nipple abnormalities such as retraction or discharge. The presence of any of these findings raises the probability that the patient has another condition instead of or in addition to cyclic mastalgia.

Noncyclic mastalgia may be caused by a variety of conditions (Box 127.2). It may be constant or intermittent, but it is not associated with the menstrual cycle. Noncyclic mastalgia tends to be unilateral and localized to a discrete area. Women with noncyclic breast pain are generally older than 40 years, and the cause is likely to be related to anatomic lesion in the breast. It is rare for breast cancer to have pain as the sole initial symptom.

Extramammary breast pain can arise from the chest wall or from other sources. Although most of the conditions that cause isolated breast pain are not immediately life-threatening, some emergency conditions, including acute coronary syndrome and pulmonary embolism, can be accompanied by pain that appears to be originating from the breast.

Mondor disease (Fig. 127.2) is a superficial phlebitis of the lateral thoracic, thoracoepigastric, or superior epigastric vein. It typically occurs in middle-aged women. The condition can be unilateral or bilateral. It is often idiopathic but may be associated with other conditions. The classic Mondor cord is 2 to 3 mm in diameter and typically red and tender, tracks from the lateral margin of the breast across the costal margin, and extends from 2 to 30 cm. Any tenderness should resolve within weeks, but the cord may remain palpable for up to 6 months. There is no risk for systemic embolization.

Dermatologic Changes and Discharge

A wide variety of skin conditions can affect the breast, nipple, or both; the most threatening and most common

**Fig. 127.1** The breast contains approximately 20 glandular units (lobes), each composed of a tubuloalveolar gland and adipose tissue. (From Iglehart JD, Kaelin CM. Diseases of the breast. In: Townsend CM, Beauchamp RD, Evers BM, et al, editors. Sabiston’s textbook of surgery. 17th ed. Philadelphia: Saunders; 2004.)
Inflammatory Breast Cancer
Inflammatory breast cancer is the breast malignancy most likely to be manifested with acute changes. It accounts for 4% of invasive breast cancers and typically develops from invasive ductal carcinoma. It is associated with particularly high mortality. Patients may have rapid, unilateral breast enlargement because infiltration of the dermal and intramammary lymphatics by tumor causes an inflammatory response. The breast typically exhibits tenderness, erythema, warmth, and the classic peau d’orange appearance. Nipple retraction or flattening is common. In one half of cases an underlying mass is detectable.

Necrotizing Fasciitis
Although patients with necrotizing fasciitis are usually found to be quite ill systemically on initial evaluation, examination of the breast may show only mild changes suggesting the location of the disease. Signs of inflammation with changes in skin color from red to dusky blue along with severe pain disproportionate to the findings on examination, particularly in a patient with significant systemic toxicity, should increase suspicion for necrotizing fasciitis.

Risk factors include advanced age, diabetes mellitus, peripheral vascular disease, acquired immunodeficiency syndrome (AIDS), and use of immunosuppressive medications, including steroids, cytotoxic agents, and antirejection medications.

Dermatitis
Dermatitis of the breast and nipple-areola complex is common and may be caused by a number of benign and malignant conditions. Frequently, the clinical history and physical examination will yield the probable diagnosis.

Nipple eczema is the most common manifestation of atopic dermatitis involving the breast. The patient typically complains of burning and itching. Examination of the breast may reveal erythema, erosions, weeping, crusting, fissures, or lichenification. The condition is often bilateral. In
breastfeeding women, nipple dermatitis tends to develop after initiating supplemental foods, probably as a result of an allergy to food residue in the infant’s mouth.

The signs and symptoms of allergic contact dermatitis of the breast are similar to those of atopic dermatitis. Triggers include soaps, shampoos, detergents, or body lotions. Most ointments available for use in lactation contain ingredients that can induce allergic contact dermatitis.

Irritant dermatitis of the nipple—“jogger’s nipple”—is common in long-distance runners; during a marathon, up to 15% of runners will experience this problem. The repetitive friction between the runner’s shirt and nipple can cause painful, erythematous, crusted erosions of the nipple and areola.

**Candidal Breast Infections**

*Candida albicans* intertrigo is a common skin condition, especially in the inframammary area. The nipple-areola complex may be involved as well, particularly in lactating women. The rash is often beefy red with typical satellite lesions. Pruritus and maceration are common.

**Nonpuerperal Mastitis and Abscess**

Recent evidence suggests that ductal ectasia and periductal mastitis are really two distinct inflammatory entities. Ductal ectasia is minimally inflammatory, generally asymptomatic, and characterized by normal aging and dilation of the subareolar ducts. Occasionally, a mass may be palpated. In contrast, periductal mastitis is a symptomatic inflammatory condition seen especially in middle-aged female smokers and has the following characteristics: fistular or erosive lesions in the periareolar area, erythema and peau d’orange appearance, axillary adenopathy, and nipple discharge.

Periductal mastitis may be confused with cellulitis, abscesses, or inflammatory breast cancer. Approximately 90% of nonpuerperal breast abscesses are subareolar.7

**Piercing-Related Infections**

Infection within the first year following nipple piercing is common (incidence as high as 20%) and is of special concern in patients who are immunosuppressed. Other high-risk patients are those who have previously undergone breast augmentation or surgery for congenital heart defects. Nipple piercing, especially in these high-risk patients, can lead to endocarditis or sepsis.

**Nipple Discharge**

Discharge from the nipple is a common complaint. Nipple discharge is often categorized according to the following factors: color, unilateral versus bilateral, number of ducts involved, and whether the fluid requires pressure for expression. In the absence of a mass, most physiologic discharge is yellow, milky, or green; occurs bilaterally from multiple ducts; and is seen only with compression. Other types of physiologic discharge include persistent lactation in women for up to 3 months postpartum or for as long as 2 years after discontinuation of lactation.

Galactorrhea may be caused by hyperprolactinemia secondary to medications, medical conditions, or a pituitary adenoma. Nipple discharge that is spontaneous, unilateral, localized to a single duct, and either clear or bloody is pathologic and requires outpatient follow-up. The most common cause of bloody discharge from a single duct is a benign intraductal papilloma.

**Mammary Paget Disease**

Paget disease of the nipple (Fig. 127.3, A and B), first described by James Paget in 1874, is a neoplastic condition that accounts for 2% to 4% of breast malignancies. The lesion involves the nipple-areola complex and may spread to the surrounding skin. Patients with early disease may have only a burning and itching sensation around the nipple area. A central palpable breast mass is present in 60% of cases.7 Patients with mammary Paget disease usually undergo mastectomy with either lymph node dissection or sentinel node biopsy.

**Skin Necrosis**

Warfarin-induced skin necrosis is a rare complication of oral anticoagulant therapy that affects only 0.01% to 0.1% of patients who take the medication.8 The typical patient is a middle-aged, obese woman who recently initiated Coumadin therapy, although cases have been reported occurring well into a year of therapy.

The lesions can be single or multiple and are accompanied by intense pain.

**MASSES**

Although breast pain is the most common symptom causing women to seek medical care related to their breasts, a palpable breast mass is associated with significant anxiety and

Breast Cancer

Emergency physicians (EPs) are in a unique position to provide education about breast cancer and screening (Box 127.4) to many women who do not have other contact with the health care system,

Breast cancer is exceedingly rare in women younger than 20 years and accounts for only a small fraction of a percent of breast disease in women younger than 30 years. Most women younger than 35 years with a solitary painless breast mass will have a fibroadenoma (see Table 127.1 for a comparison of benign breast tumors). Common benign breast masses include fibroadenomas, cysts, phyllodes tumors (malignant 5% of the time), and intraductal papillomas. Other benign tumors found in breast tissue, but not limited to the breasts, include lipomas, hamartomas, hemangiomas, neurofibromas, granular cell tumors, and fat necrosis. None of these conditions appear to increase the risk for subsequent development of breast cancer.

COMPICATIONS OF BREAST CANCER Patients undergoing treatment of breast cancer frequently visit the ED because of complications related to their disease or treatment. Breast cancer metastasis commonly includes local, regional, and distant sites: lung, pleura, pericardium, bone, and brain.
Because breast cancer is the most common extrathoracic primary neoplasm that causes metastases to the heart and pericardium, the EP should facilitate emergency echocardiography when managing a patient with breast cancer and symptoms consistent with pericardial effusion.

The development of back pain in a woman with a history of breast cancer should prompt initiation of diagnostic studies and treatment of cord compression. The most sensitive imaging study is magnetic resonance imaging, and it should be performed for back pain even when no associated neurologic finding is present (waiting for symptoms to appear may be too late).

Most patients who are treated for breast cancer undergo surgery that includes some degree of lymph node dissection. Lymphedema affects 10% to 30% of women who undergo axillary lymph node dissection; radiation and infection increase the risk. Lymphedema may range from mild to severe and can develop even years after treatment. Those at risk for the development of lymphedema are encouraged to have blood drawn and intravenous lines placed in the unaffected arm. It is usually permanent, although a few institutions have reported success with autologous lymph node transplantation.

Women who choose lumpectomy or partial mastectomy usually undergo 6 weeks of external beam radiation therapy. Radiotherapy may also be given in the form of radioactive seeds placed at the tumor site. In another method, a saline-filled balloon is placed in the lumpectomy site and radioactive material is instilled and drained twice daily for 5 days. Regardless of the radiation method, the most common complications are radiation-induced dermatitis (90% of patients), which can progress to dry desquamation (50% of patients) in the first few weeks, and moist desquamation (<10% of patients), which appears within 3 to 6 weeks. A corticosteroid cream such as mometasone furoate can be used as prophylaxis or treatment of dry desquamation, preferably in consultation with a medical or radiation oncologist. Wet desquamation, a partial-thickness injury, is best treated with hydrocolloid dressings and should be managed in consultation with a plastic surgeon or radiation oncologist.

Late effects of radiation may develop months or years after therapy. Pneumonitis is typically manifested as cough, fever, and shortness of breath 1 to 10 months after completion of radiation therapy. Radiographic changes, which can start as diffuse haziness and progress to patchy consolidations, are generally confined to the field of radiation. Dermal necrosis is a complication that may develop years after treatment. Radiation-induced brachial plexopathy, which may develop up to 30 years after breast cancer therapy, is a permanent debilitating condition that can progress to complete sensory and motor impairment of the ipsilateral upper extremity and chronic neuropathic pain.

Adverse reactions to chemotherapy are beyond the scope of this chapter. However, the EP should be aware of all drugs being used by the patient. In addition, the EP should always query patients about their use of complementary and alternative medicine.

**TRAUMA**

Trauma to the breast can be divided into the traditional divisions of blunt and penetrating. All but the most minimal trauma to the breast will require additional consideration of disruption of the underlying structures. The breast tissue itself may diminish the utility of physical examination in accurately identifying pathology.

Blunt trauma to the breast rarely appears in isolation. Multiple thoracic injuries are typical. Mandatory three-point lap-shoulder restraint laws have been effective in decreasing overall mortality from motor vehicle crashes; however, there has been a concurrent increase in the incidence of soft tissue injury to the chest wall. The chest restraint belt produces both shearing and compressive force. Simple hematomas are the most common problem after trauma. Although these hematomas typically resolve spontaneously, they may recur and become infected, even months after an injury.

Crush injuries from seat belts that involve the breast have, in rare cases, caused subcutaneous transection of the breast. A permanent furrow deformity may result. Because the breast is mobile over the pectoral fascia, sudden forceful movement of the breast can also cause complete avulsion of the breast from the chest wall and potentially rupture the perforating arteries to the breast. A transected artery may bleed massively immediately or may retract into the pectoral musculature and result in life-threatening hemorrhage after the vascular spasm resolves.

**Fat Necrosis**

The most common long-term complication after trauma to the breast is fat necrosis. Fat necrosis is an inflammatory condition that is typically a sequela of trauma, but it may also develop following surgery, infection, or radiation therapy. Women with pendulous breasts seem to be at higher risk for fat necrosis. The pathophysiology is multifactorial but primarily involves the breakdown of fat cells by blood and
tissue lipases. Clinically, mammographically, and sonographically, the condition may mimic carcinoma of the breast. Usually, a firm, poorly mobile, nontender mass is present in the superficial subcutaneous tissues. The overlying skin may be erythematous, ecchymotic, or indurated. Axillary lymphadenopathy and nipple retraction may be present. Fat necrosis typically resolves spontaneously but requires biopsy to reliably differentiate it from malignancy.

**PERIOPERATIVE COMPLAINTS**

More than 2 million women in the United States have undergone breast augmentation. Although 80% of augmentations are performed purely for cosmetic reasons, the 20% representing reconstruction following mastectomy account for a disproportionate percentage of local complications. Roughly 30% will require additional surgeries within 5 years. 

Postoperative pain can be prolonged; 30% to 40% of patients report significant pain 1 year after reduction or augmentation mammoplasty, and the number is higher after mastectomy with reconstruction. Phantom breast pain after mastectomy occurs in up to 12% of patients 1 year after surgery.

**Seroma or Hematoma**

The most common perioperative complication after any type of breast surgery is a seroma, or collection of serous fluid. On physical examination, the accumulation is manifested as a soft, movable mass with no evidence of infection and a “water bed” consistency when depressed and released. Seromas typically appear 7 to 10 days after surgery or 1 to 2 days after removal of a drain; in most cases they will resolve independently as the fluid is absorbed into surrounding tissues. A persistent, untreated seroma can lead to infection or skin flap necrosis. Hematomas may also occur after surgery, and management depends on multiple factors, including size and when they develop in relation to surgery.

**Galactorrhea**

In the first days of recovery from surgery, 1% of women will experience galactorrhea (inappropriate lactation). This figure is slightly higher in women who have previously breastfed.

**Capsular Contracture**

In capsular contracture, tightly woven collagen fibers form about an implant; they represent the body’s attempt to isolate the implant from endogenous tissue. In 15% of women, this capsule becomes hard and resistant, contracts around the implant, and causes pain, deformation, and rupture. The risk is greater in women who experienced perioperative seroma, hematoma, or infection and in those who opt for silicone implants or subglandular placement.

**Rupture**

The median life span of an implant is approximately 16 and 10 years for silicone gel and saline prosthetics, respectively. Although most ruptures do not result from ascertainable trauma, they have been reported following mammography, motor vehicle collisions, gunshots, falls, and surgical procedures in the chest, including central venous catheter insertion and thoracostomy. Clinical examination alone is unsatisfactory to identify most ruptures and should be supplemented with magnetic resonance imaging (90% accurate) or computed tomography (80% accurate).

**Infection**

Many surgeons advocate perioperative antibiotic prophylaxis. This precaution has decreased the rate of postoperative infections, which otherwise ranges from 2% to 4% within the first month. The highest risk for infection occurs in patients who choose reconstruction at the time of mastectomy. The most common pathogen is *Staphylococcus aureus* (75%), followed by *Staphylococcus epidermidis* (10%). Toxic shock syndrome has been reported in some patients after augmentation or explantation; patients exhibit sudden pyrexia (>102°F), swelling of the infected breast, vomiting, diarrhea, dizziness, and often a sunburnlike rash.

**LACTATION AND PUERPERAL CHANGES**

**Puerperal Mastitis**

Puerperal mastitis, or mastitis that develops while breastfeeding, is a common cause of premature cessation of lactation and results in voluntary discontinuation of breastfeeding in up to 25% of patients. It develops in about one third of nursing mothers. Eighty percent of cases occur in the first 3 months of lactation. Mastitis can rarely progress to abscess formation; this is significantly more common in the first 6 weeks after birth. Risk factors for puerperal mastitis include older age, primiparity, nipple damage, employment outside the home, ineffective nursing technique, and milk stasis.

Symptoms of puerperal mastitis include a painful, erythematous area or mass on the breast and systemic symptoms of fever, chills, malaise, and myalgia. The most common causative organism is *S. aureus*, although other organisms have been identified and infections may be polymicrobial. Fungal infection in the lactating breast is more common than was previously thought. *C. albicans* is the most frequently identified organism.

Differentiating between mastitis and abscess is important, and it is possible that the two conditions exist on a continuum. However, making the appropriate distinction is significant because the treatment for each is markedly different. Although an abscess is usually associated with significant fluctuance, it may appear as only a focal induration. Ultrasonography of the affected area should be performed to identify a subcutaneous fluid collection.

**Risks Associated with Lactation in Special Circumstances**

Breastfeeding is superior to manufactured infant formula for its nutritional, cognitive, emotional, and immunologic benefits. Not all medications contraindicated during pregnancy are similarly dangerous to the nursing infant. Inappropriate cross-referencing of drug information in pregnancy to lactation may result in early cessation of lactation. Similarly, not all maternal infections necessitate cessation of lactation (Table 127.2).

On average, 1% to 2% of a maternal dose of a drug is delivered to the infant, although the amount varies depending on the drug. Because the milk compartment is bidirectional, a drug that peaks in milk after 30 minutes may leave the milk compartment before the next feeding. It is therefore recommended that when possible, a nursing mother take medications immediately after a feeding to decrease the amount delivered to the infant in the next feeding. Little evidence-based data are available to determine which drugs are safe to use in lactation. EPs concerned about the safety of a particular
medication in a lactating woman can consult the American Academy of Pediatrics Committee on Drugs.20

Administration of radioactive compounds to a lactating mother may require temporary cessation of breastfeeding (Table 127.3). Expression and discarding of milk for the duration of five half-lives are recommended. When ordering a nuclear medicine study for a lactating woman, the EP should speak directly to the nuclear medicine radiologist to determine whether a radionuclide with a shorter half-life could be used.

## TREATMENT

### MASTALGIA

Most patients require only mild analgesics, such as acetaminophen or ibuprofen. Discomfort from Mondor disease can also be managed with warm compresses. A number of alternative potential treatment modalities are available to women with cyclic mastalgia21 (Box 127.5). Women with severe cyclic mastalgia, despite treatment with conservative measures, should be referred to an endocrinologist or reproductive specialist. All patients with mastalgia should receive follow-up care.

### DERMATOLOGIC CHANGES AND DISCHARGE

All patients with new onset of a dermatologic breast condition require outpatient follow-up regardless of their ED course. In particular, patients who fail to respond to traditional therapy should receive prompt evaluation and work-up for possible inflammatory breast cancer.

Local infections such as mastitis may be managed with oral broad-spectrum antibiotics; amoxicillin–clavulanic acid or levofloxacin with metronidazole is an appropriate regimen. All but the simplest abscesses require the consultation of a breast surgeon, admission for parenteral antibiotics (appropriate choices include cephalexin, doxycycline, gentamicin, and trimethoprim-sulfamethoxazole), and definitive surgical care.

Patients with any findings suggestive of necrotizing fasciitis or skin necrosis require prompt surgical consultation. Broad-spectrum antibiotics and early, aggressive surgical débridement are necessary to minimize mortality in patients with necrotizing fasciitis. Emergency management of skin necrosis includes cessation of warfarin therapy, administration of vitamin K along with fresh frozen plasma, and initiation of heparin if anticoagulation is necessary.

Patients with dermatitis can typically be discharged safely. Management includes topical steroids, lubricants, friction-reducing agents, and avoidance of atopic triggers. Close outpatient follow-up of all patients is mandatory and may include short-term reevaluation of the response to treatment.

MASSES
A physical examination that demonstrates any of the following necessitates prompt surgical referral: axillary or supraclavicular lymphadenopathy, rash, ulceration or dimpling, and nipple changes or discharge. Women without these worrisome findings still need referral for outpatient evaluation and follow-up, although many can be managed in a primary care setting. All women older than 35 years with masses require triple testing in the outpatient setting, including clinical evaluation, mammography with or without ultrasonography, and biopsy.

TRAUMA
Simple hematomas can be managed conservatively with analgesics and instructions to wear a tight-fitting bra. Caution must be exercised in patients with an acute injury and an expanding hematoma, particularly those who have coagulopathies or are taking anticoagulant medication. Prompt reversal of anticoagulation should be considered. Patients initially seen more than 48 hours after sustaining an injury seldom have bleeding from a discrete vessel and only rarely are amenable to surgery.

Findings consistent with avulsion or transection require immediate surgical consultation. Further studies should be expedited to ascertain the true extent of the injuries. Patients will require admission for definitive care.

Hematomas occasionally occur spontaneously or in the setting of very minor trauma in women with breast cancer, and they may be the first symptom of occult malignancy. Breast trauma normally heals within 4 to 6 weeks. Symptoms that persist require evaluation for possible malignancy.

Penetrating trauma to the breast warrants careful scrutiny, and all but the most superficial injuries require consideration of intrathoracic penetration. Most wounds that penetrate the full dermis and all that affect the nipple should receive the attention of a breast surgeon.

Management strategies in patients with an infected hematoma include antibiotics and drainage (either open or guided by ultrasound). Appropriate antibiotics include first-generation cephalosporins or an antistaphylococcal penicillin.

PERIOPERATIVE COMPLAINTS
Local infections may be treated with first-generation cephalosporins. Toxic shock is clearly a more significant progression of the infection and requires immediate surgical removal of the prosthesis, surgical débridement of surrounding tissue, parenteral antibiotics, and admission to an intensive care unit.

Seromas, hematomas, contractures, and ruptured implants all require consultation with a breast surgeon for definitive treatment and assurance of appropriate follow-up care.

Persistent or painful seromas or those that compromise surrounding tissue may require fine-needle aspiration. Because drainage may result in rupture of the prosthesis, aspiration is best performed by a plastic surgeon.

Hematomas seen within 48 hours of breast surgery may require additional surgery or drainage. Hematomas initially seen later than 48 hours after surgery are best managed conservatively with a cold compress or a compressive bra. Patients should avoid aspirin and ibuprofen because these medications can exacerbate the bleeding. As with seromas, there is a possibility of associated infection, and draining of the hematoma should be left to the discretion of the surgeon.

Gallactorrhoea is a benign symptom that should resolve spontaneously after a few days. Bromocriptine can be administered if the symptoms are persistent and bothersome.

In cases of capsular contracture in which notable breast hardness and distortion are present, surgery may be required to remove the implant via open capsulotomy. The patient should be counseled that manual manipulation of the breast to sever resistant fibrous capsules is not advised because it can lead to rupture.

Saline implant rupture rarely requires emergency intervention because the saline is quickly absorbed into surrounding tissue. Patients should be referred to a plastic surgeon for removal of the silicone lumen and cosmetic correction of breast deflation. Following rupture of a silicone gel–filled implant, however, extruded silicone may cause localized inflammation or silicone granulomas (silicomas) that can migrate as far as the lower part of the back, groin, abdomen, and upper extremities.

PUERPERAL MASTITIS
If mastitis is suspected, a 10-day course of oral therapy with dicloxacillin (500 mg four times daily) or cephalixin (500 mg four times daily) is indicated; either may be given as 1 g twice daily for increased compliance. Penicillin-allergic patients can be treated with clindamycin (300 mg four times daily) for 10 days. The patient should be instructed to continue breastfeeding, even on the affected side. If breastfeeding is painful, she should pump the affected breast frequently.

If an abscess is identified or suspected, oral or parenteral antibiotics may be prescribed, depending on the extent of tissue involvement, degree of systemic toxicity, and host

**BOX 127.5 Adjuvant Treatment of Cyclic Mastalgia**

- Improvement in mechanical support with a properly fitting bra and use of a sports bra during exercise
- Application of warm compresses or ice packs
- Decreasing dietary fat to less than 20% of energy intake
- Eliminating caffeine in the diet
- Smoking cessation
- Oral contraceptive pills with low estrogen content
- Parenteral medroxyprogesterone acetate (Depo-Provera)
- Micronized progesterone vaginal cream applied to the breast
- Vitamin E
- Acupuncture

---
factors. Parenteral choices include nafcillin (2 g intravenously [IV] every 6 hours), cefazolin (1 g IV every 8 hours), and vancomycin (1 g IV every 8 hours). Patients should pump and discard all milk until the abscess has healed to prevent transmission of the infection to the infant. Although aspiration with a 16-gauge needle may be performed, surgical consultation is required for definitive care.

Patients must have close follow-up and should be instructed to return to the ED if the symptoms worsen at any time or fail to improve within 48 hours. Additional management may include referral to a lactation specialist, if available.

Indications for possible inpatient admission include failure of outpatient therapy, infections in immunocompromised patients (AIDS, diabetes, therapy with cytotoxic agents or glucocorticoids), and patients with significant signs of systemic toxicity. Rarely, sepsis, gangrene, or necrotizing soft tissue infections can develop.

**PATIENT TEACHING TIPS**

Any new breast symptom requires evaluation by a physician:

- the patient should seek prompt reevaluation if initial treatment of a diagnosed condition is not effective.

Although most causes of breast lumps, skin changes, breast pain, and nipple discharge are benign, many conditions (including malignancy) appear similar on physical examination and even on imaging studies.

Making a definitive diagnosis of any breast condition may require several follow-up outpatient visits and tests.

Patients should be familiar with the American Cancer Society’s recommendations for breast cancer screening for their age group.

Most patients fail to appreciate the significance of the false-negative rate of mammography. Mammograms fail to diagnose breast cancer in up to 15% of cases; therefore, a recent “normal” screening mammogram should not falsely reassure a patient with a suspicious complaint. Tissue sampling is indicated in these situations.

Patients who have undergone surgery or radiation therapy (or both) for breast cancer are at high risk for the development of lymphedema. They should be instructed to avoid compression of the ipsilateral arm and should seek immediate medical care for the treatment of insect bites, burns, lacerations, and infections, all of which increase the risk for lymphedema.

**SUGGESTED READINGS**

**DOCUMENTATION**

Meticulous documentation of the physical examination, as well as all results, when evaluating a patient with a complaint related to the breast or when an abnormality is discovered incidentally is a necessity.

Documentation of the physical examination should include the appearance of the breasts, including the nipple-areola complex, with the patient sitting, with the arms raised, and supine. Results of palpating the breast with the patient supine and the ipsilateral hand under the head should be recorded, as well as the results of gentle nipple squeezing.

All abnormalities should be diagrammed and described.

Size, mobility, consistency, and symmetry in comparison with the opposite breast are important to document. Lymph nodes should be noted in terms of number, size, consistency, and mobility.

Impeccable documentation is required in cases of suspected intimate partner violence or sexual assault.

When treating a lactating patient, all discussions about the advisability and possible risks associated with continuing breastfeeding should be documented, especially when diagnosing infectious conditions, prescribing medications, and ordering radionuclide imaging.

The history should include attention to current medications, as well as past hormonal therapy, menopausal status, reproductive and breastfeeding history, family history of cancer, radiation exposure, and previous breast problems.

An inclusive differential diagnosis should be documented, specifically listing cancer if it is a possibility. In these cases, documented discussions with the patient should include mention of the physician’s concerns and need for prompt follow-up.

Written discharge instructions should include follow-up plans and phone numbers for referral physicians. Special arrangements may be necessary to ensure timely specialist care. All such efforts should be documented.

or family member. Alternatively, she or he may be accompanied by law enforcement officers or be transported by emergency medical services. The individual may be seen immediately after or long after the assault. A sexual assault patient initially evaluated within 120 hours (5 days) of the assault should be considered a high-priority patient and be brought to a designated treatment area as soon as possible. The reason for this is manifold and includes providing crisis intervention, treating injuries, administering time-sensitive medications, and expediting the evidentiary examination to minimize loss or deterioration of forensic evidence. It is prudent for EDs to have a systematic management plan in place for these patients from triage to discharge.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

MULTIDISCIPLINARY APPROACH

Emergency physicians (EPs) are responsible for managing both the medical and forensic needs of patients with a report of sexual assault. This is best accomplished in an organized manner, such as with a sexual assault response team (SART). Members include a sexual assault forensic examiner (SAFE), victim advocates, law enforcement officers, crime laboratory personnel, and prosecutors. A SAFE has specialized knowledge and training to perform the forensic evaluation with a standardized sexual assault evidence collection kit (SAECK). Research has shown that use of a SART/SAFE program improves the quality of forensic evidence with an increase in prosecution rates over time. In jurisdictions in which such teams are unavailable, ED providers are responsible for the forensic examination, and it is therefore prudent that EPs familiarize themselves with their state-specific SAECK.

CONSENT FOR FORENSIC EVALUATION AND EVIDENCE COLLECTION

Patients should be informed of all of the options available to them, including forensic evaluation and evidence collection, depending on timing of examination. Before proceeding with any part of this evaluation, written informed consent for all aspects of the evaluation must be obtained as listed in Box 128.1. The patient has the right to refuse all or some parts of a forensic examination, and consent can be withdrawn at any time during the examination.
The clinical encounter with a sexual assault patient is unique in that two medical records are generated for one patient. One is the usual ED medical record and the other is the forensic legal record. These records serve very different purposes, and consequently what is documented in each will differ.

**HISTORY**

For the ED medical record, the history of the assault should be focused on details that affect medical management of the patient in the ED, including information that will help determine the risk for injuries and what treatment of sexually transmitted diseases (STDs) should be offered. In contrast, the forensic record is driven by strict policies and procedures and should include only medical information that has a direct bearing on evaluation of the reported crime. Material that is generally considered to constitute useful background in a therapeutic context may have a prejudicial effect in a forensic context and should not be included in the forensic record. Examples include the number of previous pregnancies, past mental health treatment, and remote substance abuse. Documentation should be concise and directly relevant to the assault, including any information that is necessary to properly interpret the current physical findings. Many SAECKs contain preprinted forms that help the examiner with the history-taking process to facilitate proper documentation. Salient features of the history that should be obtained for documentation in the forensic medical record are listed in Box 128.2.7,8

**PHYSICAL EXAMINATION**

Physical examination is necessary to evaluate for signs of any trauma sustained during the sexual assault. The reported incidence of nongenital physical injuries ranges from 23% to 85%.8-15 When injuries are sustained, those most commonly seen are soft tissue injuries involving the head, face, neck, and extremities. Blunt force trauma, including penetrative blunt mechanisms, may produce contusions, which are associated with swelling, pain, tenderness, and discoloration, and lacerations from tearing of the tissues. A friction mechanism may cause abrasions. Sharp-force trauma may produce incised wounds. Bites may involve multiple mechanisms of injury. Patterned injuries suggest the specific object, weapon, or mechanism used to produce its characteristic shape.

The physical examination should be dictated by the history of the events. Close attention should be paid to the skin for signs of victim resistance, applied restraints, or defensive wounds. The oral cavity should be inspected for a torn lingual or labial frenulum or contusions to the palate with report of an oral assault. With a report of strangulation, the examination should focus on assessing for and documenting abrasions or contusions of the neck, facial petechiae, and subconjunctival hemorrhage.

Published rates of female genitoanal injury vary widely from 6% to 65%, with most investigators reporting a range of 10% to 30%.8-15 Risk factors for injuries included examination within 24 hours of the assault, presence of nongenital injury, threats of violence, and age younger than 20 and older than 40 years.8-15 The genital structures most frequently injured as a result of a penetrative mechanism are the fossa navicularis and posterior fourchette, followed by the labia minora and hymen. It is paramount that these areas be inspected carefully during the examination.

Physical examination consists largely of gross visual inspection, which may readily miss documentable injuries. Adjuncts to assist in detecting subtle injuries include anoscopy, colposcopy, Wood lamp, and application of toluidine blue.

A large number of sexual assault patients do not sustain obvious injuries. It is important that the EP understand that the absence of objective physical or genital injury does not preclude the possibility of sexual assault. The presence of such injuries is dependent on many assault-specific and patient-specific factors, including the age of the victim, the state of the tissues such as lubrication and elasticity, the degree of force involved, and the use of objects or implements.
In addition, detection of subtle injuries is largely dependent on examiner training and experience.

For the forensic record, documentation of the physical findings should include thorough, precise written descriptions in standard anatomic position, including injury location, measured size, shape, colors, contours, and depth. In addition, the use of anatomic body maps and forensic photography is encouraged, both of which can be invaluable in court proceedings. Many SAECK preprinted forms include body maps on which to note injuries.

**FORENSIC EVALUATION: EVIDENCE COLLECTION AND CHAIN OF CUSTODY**

The premise of evidence collection in sexual assault cases is to link the victim and assailant, relate both to the crime scene, identify the assailant via a DNA profile, and establish some features of the crime. The SAECK, also known as a “rape kit,” is stocked in most hospitals and is state specific. It is used to guide the process of evidence collection within 96 to 120 hours after the assault to increase the chance of detecting spermatozoa. Seminal fluid, as evidenced by spermatozoa, high levels of acid phosphatase, or p30 prostate-specific antigen, is recovered from 38% to 48% of sexual assault patients.¹

Chain of custody, also referred to as the chain of evidence, refers to detailed documentation of the trail of the evidence from the time that it is collected until it is exhibited during a legal trial. To comply with the chain of custody, the kit must be accounted for at all times without failure, and all transfers must be documented, including the police officer who assumes responsibility for the kit. If police are unavailable to collect the kit at that point, it should be locked in a secure area reserved for such instances so that the data are not invalidated. If there are any gaps in the chain of custody, the evidence may not be admissible in court. It is prudent for EDs to develop protocols for these encounters.

**TIPS AND TRICKS**

**Forensic Evaluation**

SART/SAFE programs coordinate patient care and improve evidence collection and prosecutions.

Emergency physicians should familiarize themselves with the SAECK used in their jurisdiction.

If the patient wants something to drink before the forensic evaluation has started and she consents, collect the oral swabs first and be sure to maintain chain of custody.

If the patient wants to urinate before the forensic evaluation has started, give her a collection cup for the urine pregnancy test and toxicology screen, and inform her not to wipe the genital area afterward. Be sure to maintain chain of custody of this sample.

**DIAGNOSTIC TESTING**

Although selection of the initial laboratory studies and radiographic imaging is guided by the trauma assessment, certain tests should be ordered for all sexual assault patients. All female sexual assault victims should undergo urine pregnancy testing because a positive result will alter the choices for prophylaxis. If nonoccupational postexposure prophylaxis (nPEP) will be administered, a baseline complete blood count, liver function tests, and blood urea nitrogen and creatinine levels should be ordered before initiation. If the patient is initially seen many days after the assault and has symptoms...
and signs suggestive of active infection with an STD, culture for gonorrhea and Chlamydia should be obtained in addition to a vaginal wet mount and culture for Trichomonas and bacterial vaginosis (BV). Further testing should be reserved for an outpatient follow-up appointment, including human immunodeficiency virus (HIV) antibody testing, syphilis testing, hepatitis B and C serology, and gonorrhea and Chlamydia screening.

The influence of drugs must be considered in each sexual assault case. Samples for hospital toxicology screening should be drawn only if they affect medical management of the patient. During the forensic examination, if the patient is amnestic and DFSA is suspected, urine and blood should be collected with the victim’s consent for a forensic drug screen for assaults occurring less than 72 to 96 hours before the evaluation. These samples are considered forensic evidence, and the chain of custody should be maintained at all times for analysis in the crime laboratory, not in the hospital laboratory.

**MANDATORY REPORTING**

Laws regarding mandatory reporting of adult sexual assault victims vary from state to state and can be broken down into laws that specifically require providers to report treatment of a rape victim to law enforcement, laws that require reporting of injuries that may include rape, laws relating to other crimes or injuries that may have an impact on rape and sexual assault victims, and laws regarding sexual assault forensic examinations that may affect rape and sexual assault reporting. It is prudent for EPs to be well informed of the local reporting regulations in their jurisdictions.

**CONSULTATION**

A multidisciplinary approach to the care of sexual assault patients is prudent to optimize medical care and forensic and legal considerations. In patients with significant physical or genital trauma, consultation with trauma surgery and gynecology should be considered. The local victim advocacy group and hospital social worker should be consulted for patient support. A SAFE should be consulted for forensic evaluation and evidence collection once the patient consents to this course of action. For patients who are at high risk for HIV, consultation with an infectious disease (ID) specialist is important to facilitate the best nPEP regimen based on the characteristics of the assault.

**TREATMENT**

**PREHOSPITAL MANAGEMENT**

Prehospital care should proceed as usual with medical stabilization and treatment of injuries. In clinically stable victims without significant injury, it is best practice for the prehospital providers to minimize touching the patient so that potential forensic evidence is not altered. If the sheet that the patient is transported on contains foreign material, it should be folded up and given to the responsible clinical staff member in the ED for possible inclusion in the evidence collection kit while maintaining the protocol for chain of custody.

**HOSPITAL MANAGEMENT**

A patient with a report of sexual assault may go to the ED immediately after or long after the assault. The time since the assault determines how these patients are managed, including what interventions and treatments are recommended. Figure 128.1 outlines the scope of evaluation and treatment of sexual assault based on the timing of initial evaluation.

Sexual assault is a disempowering experience, and giving patients options about their management and treatment is important in supporting the process of recovery. If conducted in a sensitive and supportive way, the ED encounter may be the first step toward healing. The local victim advocacy group should be notified, with patient permission, so that an advocate can come to the ED to provide support, crisis intervention, and information to the patient.

**Medical Stabilization and Management of Physical Injuries**

Injuries related to the assault, such as soft tissue injuries and fractures, should be treated appropriately. The advanced trauma life support protocol should be followed when assessing a trauma patient. Nearly 20% of sexual assault victims require medical procedures or interventions. Tetanus prophylaxis should be considered in patients with violation of skin integrity who have not had a booster within 10 years. After treatment of the physical injuries, the focus should transition to emergency contraception, STD prophylaxis, and risk assessment for nPEP. Table 128.1 lists the recommended prophylaxis regimen for sexual assault patients. Forensic evaluation and evidence collection follow suit.

**Emergency Contraception**

Overall, the risk for pregnancy following sexual assault is 5%. The risk varies throughout the menstrual cycle, as shown in Table 128.1. Regardless of where she is in her cycle, following a negative pregnancy test, all females of childbearing age with a report of sexual assault should be offered emergency contraception (see Chapter 129 for further details).

**Sexually Transmitted Disease Prophylaxis**

The risk of acquiring an STD following a sexual assault is significant, with reported rates of 4% to 56%, depending on the circumstances of the assault. Given the difficulty in accurately assessing risk, as well as poor compliance with follow-up visits in this patient population, which has been estimated to be 10% to 35%, empiric prophylaxis should be offered routinely to these patients. STD prophylaxis should be guided by the 2010 Centers for Disease Control and Prevention (CDC) guidelines and includes dispensation of medication for prophylaxis against Neisseria gonorrhoea, Chlamydia trachomatis, Trichomonas vaginalis, BV, hepatitis B, and HIV in high-risk cases.

Table 128.1 includes the 2010 CDC-recommended regimen for STD prophylaxis after a sexual assault. Although the efficacy of these medications in preventing infections after sexual assault has not been evaluated, administration is still considered standard of care given the high single-exposure transmission rate in the case of a disease-positive assailant.

Screening for STDs in asymptomatic sexual assault patients is very controversial. Those in favor of not testing argue that a positive test represents preassault disease and could be used against a victim in court. Laws exist in every state that protect...
the victim’s previous sexual history, but if medical records are subpoenaed, the STD diagnoses may be discovered. As a result, the patient and clinician might opt to defer testing. The American College of Emergency Physicians states that in cases in which prophylaxis will be given, acute cultures are not necessary unless obvious signs of an STD are present.24,35

If the patient is seen in the ED days after the sexual assault with symptoms of active infection, including vaginal discharge or pelvic pain, a pelvic examination must be performed to assess for cervicitis and pelvic inflammatory disease. Cervical and vaginal cultures should be obtained and full treatment administered for symptomatic disease.

</tbody>
</table>

× 28 days or until the source patient is proved to be HIV negative  
*Note:* Many alternative regimens are available. Administration of an antiretroviral is highly suggested because the combination of medications listed in concert with the traumatic event may induce nausea and vomiting.

---

**Nonoccupational Postexposure Prophylaxis for Human Immunodeficiency Virus Infection**

The frequency of HIV seroconversion as a result of sexual assault is difficult to estimate but probably low. In consensual sex, the risk for HIV transmission from receptive penile-vaginal intercourse is 0.1% to 0.2% and for receptive penile-rectal intercourse is 0.5% to 3%. Various factors increase risk for HIV transmission, including trauma with resultant bleeding, site of exposure to the ejaculate, high viral load in the ejaculate, multiple assailants, and the presence of an STD or genital lesion in either party.

nPEP has not been proved to be effective in decreasing transmission of HIV in cases of sexual assault but, instead, is extrapolated from health care workers with occupational exposure. As a result, a risk-benefit analysis must be performed to determine whether this therapy should be offered.
nPEP should be considered only if the exposure occurred less than 72 hours previously, and its efficacy is maximal when administered soonest after exposure. Absolute indications for starting nPEP include initial evaluation less than 72 hours after exposure to a known HIV-positive assailant with an exposure that carries substantial risk for transmission. This will rarely be the case because the majority of sexual assault patients do not know the HIV status of their assailant. Consequently, the clinician will have to make a case-by-case determination for starting nPEP based on the characteristics of the assault. The EP should consult with an ID specialist to decide whether therapy is indicated and which regimen would be most appropriate given the assault-specific details. If one is not readily available, assistance with nPEP-related decisions can be obtained by calling the National Clinician’s Post-Exposure Prophylaxis Hotline (PEP line) at (888) 448-4911. When the decision is made to administer nPEP, the first dose should be given as soon as possible and prophylaxis continued for 28 days. nPEP is not recommended for patients initially evaluated more than 72 hours after exposure because the risks associated with the medications outweigh the benefits by this time. Table 128.1 includes the CDC-recommended regimen for nPEP after a sexual assault.

Prescriptions
As illustrated in Table 128.1, sexual assault patients may be administered multiple medications during the ED visit, the majority of which require only one dose. The exceptions are doxycycline and nPEP. If doxycycline is chosen for Chlamydia prophylaxis, a prescription for a 7-day course should be given. For nPEP, the CDC recommends a 3- to 5-day starter pack to last until the follow-up visit, at which time an additional prescription can be given if appropriate. If the patient has consumed alcohol in the last 48 hours, she should not be administered metronidazole (Flagyl) in the ED. She should be sent home with the dose or given a prescription so that she can take it when outside the window of a disulfiram-type reaction.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION
After all medical treatment and forensic evaluation are complete, the patient’s environment should be assessed for safety. The SAFE or hospital social worker can help the patient identify resources if she feels unsafe returning home. If deemed safe for discharge, a hospital aftercare packet should be given to the patient because victims of traumatic events frequently cannot remember the events immediately following a crisis. She should be given contact information for the rape crisis center or hospital counseling services because the mental health morbidity associated with sexual assault is profound.22

Within 1 to 5 days of the ED visit, the patient should follow up with an ID specialist for testing for HIV, hepatitis B and C, and syphilis. Additional counseling and support can be offered in addition to assessing for medication adherence and side effects if nPEP was started in the ED. The rest of the 28-day course of medication should then be prescribed or an altered regimen recommended if indicated by side effects. Two weeks after the ED visit the patient should follow up for STD screening. Four weeks after the ED visit the patient should follow up for pregnancy testing and receive the second dose of the hepatitis B vaccine if applicable.24,36

Note that management of pediatric sexual abuse varies significantly from the management of adult sexual assault outlined in this chapter.

Emergency Contraception
Tomer Begaz

Emergency contraception (EC) is more effective the sooner it is administered, and its effectiveness decreases with time. It can be administered up to 120 hours after intercourse with reasonable effectiveness.

EC is not effective in pregnancy, but it is also not harmful.

Progestin-only EC (levonorgestrel, “Plan B”) is more effective than combined estrogen-progestin EC and has fewer side effects.

In the United States, levonorgestrel EC (“Plan B”) is available to women older than 17 years without a prescription.

Both levonorgestrel doses (1.5 mg total) can be administered as a single, one-time dose.

Hormonal EC can cause nausea. Antiemetics can help if administered 30 to 60 minutes before taking contraceptive pills.

Because patients can still become pregnant for the remainder of the cycle after the use of EC, alternative methods of contraception must still be used, and patients should immediately resume taking their regular oral contraceptive pills.

A pelvic examination is not a prerequisite to providing EC.

Many pharmacies do not have Plan B available in timely fashion; therefore, it is prudent to give the pills directly to the patient.

Epidemiology

Emergency contraception (EC) refers to methods of preventing pregnancy that are used after sexual intercourse. Circumstances making visits to the emergency department (ED) necessary include rape, contraceptive failure (e.g., condom breakage), and failure to use a contraceptive.

Approximately 50% of women between the ages of 15 and 44 years have had at least one unwanted pregnancy, which amounts to more than 3 million unwanted pregnancies annually in the United States.1 No contraceptive method is 100% effective, and the failure rates of contraceptives are surprisingly high (Table 129.1).2 Because contraceptive failure is so common, most emergency physicians (EPs) will deal with this issue on a regular basis, and they should be aware of the indications and complications of this treatment.

Pathophysiology

The primary mechanism of action of estrogen-progestin EC is inhibition of ovulation. Additional possible contributing mechanisms include thickening of cervical mucus, altered sperm transport, and changes in the endometrial lining.3 Progestin-only methods (levonorgestrel) do not appear to have
an effect on the endometrium. Ulipristal is a progesterone receptor modulator, similar to mifepristone. The primary mechanism of these drugs at the EC dose is inhibition of ovulation, although the possibility of an additional effect on uterine implantation cannot be entirely excluded. Once an embryo is implanted in the endometrium, hormonal EC has no effect on a pregnancy and does not cause abortion.\(^6\)

It is important for the EP to understand the mechanism of action of EC to accurately address the concerns of individual patients. According to the definition of the American College of Obstetrics and Gynecology, pregnancy is established at the time of implantation of the embryo in the uterus.\(^5\) By this definition, hormonal EC drugs are not abortifacients because these medications do not interfere with already established (implanted) pregnancies. However, individual patients may have a different understanding of terms such as conception and abortion than the medical community does. The known facts should be presented to patients simply and clearly so that they will be informed participants in their health care (Table 129.2 and Boxes 129.1 and 129.2).\(^6,7\)

**PRESENTING SIGNS AND SYMPTOMS**

Patients seen immediately afterward in the ED should have no symptoms. If pregnancy or any symptoms such as abdominal pain are of concern, further evaluation is indicated. See the Red Flags box.

### RED FLAGS

Patients seen immediately after coitus should have no symptoms.

Patients requesting emergency contraception (EC) who are having medical symptoms (abdominal pain) should be evaluated for the cause of their symptoms.

If signs or symptoms consistent with pregnancy are present, a pregnancy test should be performed because EC is not effective in pregnant patients.

Patients requesting EC may be at risk for sexually transmitted diseases and should be counseled and either tested or referred for outpatient follow-up or testing.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

EC may be indicated in several circumstances, as listed in Box 129.1.

### TREATMENT

Four regimens for EC are commonly used in the United States: combined estrogen-progesterone (“Yuzpe method”), progestin only (levonorgestrel), progesterone agonist-antagonist (ulipristal), and the copper intrauterine device (IUD). A combined regimen of estrogen and progesterone

### BOX 129.1 Sample Indications for Using Emergency Contraception

- Failure to use a contraceptive method
- Dislodged, broken, or improperly used condom, diaphragm, or cervical cap
- Unprotected intercourse within 7 days of starting oral contraceptives
- Two or more missed estrogen-progesterin birth control pills
- One or more missed progestin-only birth control pills
- Removal of a contraceptive skin patch or ring
- Unprotected intercourse within 14 days of first depot medroxyprogesterone (Depo-Provera) injection
- Ejaculation on the external genitalia without reliable contraception
- Sexual assault when the woman is not using reliable contraception
- Miscalculation of the periodic abstinence method

pills for EC was first reported and popularized in the 1970s by Yuzpe et al. and is often referred to as the Yuzpe method. The standard dosing in this regimen is two 100-mcg doses of ethinyl estradiol and 1 mg of norgestrel taken 12 hours apart. When taken within 72 hours of unprotected intercourse, this regimen will prevent approximately 75% of pregnancies. This method of EC has been effectively supplanted by progestin-only methods, which are more effective and have fewer side effects. The Yuzpe method is thus primarily a historical regimen.

A preferred, progestin-only method of EC has become popular and is marketed in the United States under the brand name Plan B, which consists of two 0.75-mg doses of levonorgestrel taken 12 hours apart. The recommended approach is to take the two doses simultaneously, which increases compliance, decreases side effects, and is equally effective. The EP should instruct the patient on this method because the packaging lists only the two-dose method (Table 129.3).

Ulipristal acetate (brand name Ella) is a progesterone agonist-antagonist that became available for use in the United States late in 2010. It is available by prescription only. Its effectiveness is similar to that of levonorgestrel, and ulipristal has been found to not be inferior to levonorgestrel in two well-conducted studies. It is administered as a single 30-mg dose taken within 120 hours of intercourse. The side effect profile of Ulipristal is remarkably similar to that of levonorgestrel, with about 20% of women experiencing headache and 10% to 15% experiencing nausea or dysmenorrhea (or both). Unlike levonorgestrel, which tends to bring about the next menses sooner than expected, thus relieving the patient of the fear of being pregnant, ulipristal is associated with a delay in subsequent menses by a mean of 2 days.

Of the hormonal EC methods, levonorgestrel and ulipristal are more effective and are recommended over the Yuzpe method. The difference in effectiveness varies with the timing of treatment (Fig. 129.1). Both levonorgestrel and ulipristal are less likely to cause nausea and vomiting than combined estrogen-progestin formulations are. Other hormonal methods have been used for EC but are less popular either because of questionable efficacy (danazol) or because of a higher incidence of side effects (high-dose estrogens).

The IUD is the most effective postcoital contraceptive and prevents more than 99% of pregnancies if inserted within 5 days of intercourse. This can be an ideal form of EC in patients who prefer to continue using an IUD as their contraceptive device for an extended period. IUDs should be avoided in patients with a history of sexually transmitted disease and in those with multiple sexual partners because IUD use increases the likelihood of pelvic inflammatory disease. This drawback makes an IUD unsuitable for patients seen after rape and for adolescent patients. Other contraindications to copper IUD insertion are cervical or endometrial cancer, unexplained vaginal bleeding, and copper allergy. Patients should be informed of its marked superiority in effectiveness over other methods of EC and be referred for IUD insertion if they choose this method.

Mifepristone (RU-486) is a progesterone antagonist that is effective in EC. It functions by inhibiting ovulation, as

---

**BOX 129.2 Contraindications to and Complications of Emergency Contraception (EC)**

There are no absolute contraindications to hormonal EC. EC agents are not abortifacients, and EC is not effective in pregnancy. A urine pregnancy test should be performed before administering EC if the patient might be pregnant.

Relative contraindications to estrogen-containing EC include smokers older than 35 years and patients with a history of thrombophilia, stroke, heart attack, malignancy, deep vein thrombosis, and migraine with neurologic symptoms. In these cases, a progestin-only form of EC is recommended.

An intrauterine device should not be used by patients with multiple sexual partners or those at risk for sexually transmitted diseases.

Randomised controlled trial of levonorgestrel versus the Yuzpe regimen of combined oral contraceptives for emergency contraception. Lancet 1998;352:428-433. With permission.)

![Chart showing effectiveness of levonorgestrel versus Yuzpe method by timing of treatment](chart.jpg)
well as endometrial maturation. In the United States, a 600-mg dose of mifepristone is approved as an abortifacient for pregnancies up to 49 days. Lower doses of mifepristone, from 10 to 50 mg, are at least as effective as and probably more effective than levonorgestrel for EC and have a very good side effect profile. Mifepristone is administered as a single dose within 120 days of intercourse. The 10-mg dose is currently used routinely in several countries as EC. Mifepristone causes a 1-week delay in subsequent menses in about 20% of women who use it for EC, which understandably can cause patients anxiety. Currently, administration of mifepristone is limited to registered providers who contract with the patient to schedule three office visits. This restriction makes prescribing mifepristone in the ED impractical. Additionally, its use as an abortifacient has given the drug some notoriety that may make universal implementation a challenge in the future.

TIMING OF ADMINISTRATION OF EMERGENCY CONTRACEPTION

Hormonal EC is effective when administered up to 120 hours after intercourse. There is an inverse linear relationship between the time of administration of EC after unprotected intercourse and its effectiveness—the sooner that EC is started, the more effective it is. For this reason, it is of the utmost importance to begin EC as soon as possible. Many EDs stock levonorgestrel; if it is available through the hospital pharmacy, it can be given directly to the patient by the EP. If this is not possible, in addition to a prescription (if necessary) and instructions, the patient should be provided with a list of local 24-hour pharmacies that provide EC. It is advisable to call the pharmacies to confirm availability and expedite the preparation because as many as half of the pharmacies will not stock many forms of EC.

SIDE EFFECTS

The adverse effects of estrogen-progestin contraceptive drugs are primarily related to the estrogen component. The most common side effect is nausea, which affects half of women taking this regimen. Approximately 20% of women vomit as a result. Nausea and vomiting are significantly less common with progestin-only regimens (nausea in 18% and vomiting in 4%). The incidence and severity of nausea and vomiting can be decreased with the administration of an antiemetic 30 to 60 minutes before taking the EC agent. Meclizine (50 mg) has been used with success, but any antiemetic can be administered. If a patient vomits more than 1 hour after taking an EC drug, the dosage does not need to be repeated.

A common side effect of all regimens is vaginal spotting; between 10% and 20% of patients report this symptom. Spotting should resolve without intervention and does not indicate failure of this method. Breast tenderness is another side effect of EC, particularly of estrogen-progestin methods, and can be troublesome because it is also an early sign of pregnancy. Patients should be advised to have a pregnancy test if their next period is not normal and they have signs of pregnancy.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

ACCESS TO EMERGENCY CONTRACEPTION

On April 22, 2009, the U.S. Food and Drug Administration approved over-the-counter sales of levonorgestrel, packaged as Plan B, for women 17 years or older. Men with proof of age could also buy Plan B for a partner. Women younger than 17 years can still purchase EC with a prescription. Because over-the-counter availability is unlikely to change the reluctance of many pharmacies to stock Plan B and provide it in timely fashion, administration of EC in the ED is recommended to ensure patient access. Increased knowledge about the availability of EC methods is likely to increase the number of adolescents younger than 17 years who access the ED for Plan B.

Patients should be advised of the common side effects of EC. More serious symptoms such as fever, severe abdominal pain, and heavy bleeding should not be attributed to EC, and patients should be advised to be reevaluated for serious symptoms.

Patients should be told to use barrier protection or resume taking oral contraceptive pills (or both). If they have not been tested for sexually transmitted diseases in the ED, patients should follow up with a primary care provider for counseling and testing. For the majority of women, their next menstrual period should fall within 1 week of the time that the menstrual period is regularly due. The patient should be instructed to have a pregnancy test if the menstrual cycle is delayed by more than 1 week.

Patients should be advised that the actual effectiveness of EC depends on the timing of administration so that they understand that EC is not 100% effective even when taken as directed (see Table 129.2).

Heat-Related Emergencies

Virgil Davis

SECTION XIII ENVIRONMENTAL DISORDERS

KEY POINTS

- Heat stroke is a life-threatening hyperthermic syndrome characterized by central nervous system dysfunction and associated multisystem organ failure.
- The main goal of therapy is rapid reduction of the patient’s core temperature to about 39° C with one of two methods—evaporative cooling or cold water immersion.

PERSPECTIVE

Heat-related injury spans a wide spectrum from the unpleasant and transient conditions of heat cramps or prickly heat to the life-threatening multisystem organ failure of heat stroke. The most important risk factors for heat illness are listed in Box 130.1. Mechanisms of acclimatization are listed in Table 130.1.

EPIDEMIOLOGY

Roughly 688 people die yearly of heat-related causes, Arizona has the highest incidence at 1.7 per 100,000, followed by Nevada (0.8 per 100,000) and Missouri (0.6 per 100,000). An estimated half of the deaths are weather related, and 5% result from being enclosed in motor vehicles, boiler rooms, or kitchens; in the remaining cases, the causes are unspecified. Mortality from heat stroke with appropriate treatment is reported to be between 0% and 28%.

PATHOPHYSIOLOGY OF HEAT STROKE

Severe heat illness is thought to result from three main mechanisms: physiologic alterations in response to hyperthermia, direct cytotoxic effects of heat, and inflammatory and coagulation responses of the host, which interact to create a spiraling deterioration resulting in circulatory collapse and multisystem organ failure.

Failure of thermoregulation occurs when fluid and electrolyte replacement is inadequate; it results in diminished cardiac output, hypotension and acute renal failure, and shunting of blood away from the splanchnic circulation, which leads to intestinal ischemia. Increased gut permeability and the entrance of endotoxins stimulate additional inflammatory mediators.

Heat itself has a direct cytotoxic effect and causes cell death over a period of 45 minutes to 8 hours at body temperatures of 41.6° C to 42° C; below these temperatures, cell death can still occur through apoptosis.

Heat induces higher production of numerous inflammatory cytokines that contribute to the neuronal injury and hypotension seen in patients with heat stroke, and it results in coagulation and endothelial cell injury, which can lead to disseminated intravascular coagulation and greater vascular permeability.

Figure 130.1 diagrams the current understanding of the pathophysiology of heat stroke.

MINOR HEAT-RELATED SYNDROMES

PRESENTING SIGNS AND SYMPTOMS

As stated earlier, heat-related illness is a continuum. Table 130.2 summarizes the various types of heat illness.

HEAT EDEMA

Heat edema is a self-limited illness characterized by mild swelling of the hands and feet as a result of increased interstitial fluid after heat exposure.

PRICKLY HEAT

Clogging of the sweat glands leads to an erythematous, maculopapular, and pruritic rash commonly called prickly heat.

HEAT SYNCOPE

Heat syncope results from heat-induced volume depletion and peripheral vasodilation, which often occur in people with decreased vasomotor tone, such as the elderly, and in people poorly acclimated to the heat. It is important to regard heat syncope as a diagnosis of exclusion and to evaluate for other plausible causes of syncope. In addition, the emergency physician (EP) should remember to evaluate for any injuries sustained during a fall as a result of syncope. The patient should have a rapid response to hydration. Electrolytes should be evaluated in patients with signs of volume depletion.
HEAT CRAMPS
Heat cramps are involuntary muscle spasms, most commonly of the calves, thighs, or shoulders, that occur either during or after vigorous physical activity. Cellular hyponatremia and hypokalemia are thought to cause this problem. Rhabdomyolysis is a very rare complication that can result from prolonged muscle spasm.

TREATMENT
Most minor heat-related syndromes are mild and require simple or no treatment. Treatment is summarized in Table 130.2 for these conditions.

BOX 130.1 Risk Factors for Severe Heat Illness
- Extremes of age (children and people 65 and older)
- Alcohol and drug intoxication
- Impaired cardiac function
  - Illness (e.g., heart failure)
  - Drug therapy (e.g., beta-blockers)
- Dehydration
- Exertion
- Anhydrosis from the use of anticholinergic agents or phenothiazines
- Intercurrent illness
- Psychiatric illness
- Stimulants
- Lack of air conditioning
- Lower socioeconomic status.

HEAT STROKE
Exertion or heat exposure → Heat stress → Thermoregulatory response → Splanchnic vasostenosis → Intestinal ischemia → ↑ Intestinal wall permeability → Endotoxemia → Heat stroke and circulatory shock.

Sweating → Vascular permeability → Coagulation cascade → Renal failure → Intestinal ischemia → ↑ Intestinal wall permeability.

PATIENT TEACHING TIPS

Heat Illness
The three main types of heat illness are heat cramps, heat exhaustion, and heat stroke.

Heat cramps are painful muscle spasms and a mild form of heat illness that occur when you sweat too much or do not drink enough fluids.

Heat exhaustion is due to dehydration and is more serious.

Heat stroke is marked by severe dehydration and confusion secondary to overheating; it is life-threatening.

Prevention
During hot weather:
- Reschedule strenuous activities to cooler times of the day.
- Reduce your overall level of physical activity.
- Drink additional water or electrolyte solution (sports drink).
- Wear lightweight and light-colored clothing.
- Increase time spent in air-conditioned environments.
- Frequently check the elderly, homebound, or disabled people, all of whom are at greater risk for heat illness.

Children
Never leave children enclosed in motor vehicles. Yearly, 30 to 40 children die of heat stroke after being left in cars.

Athletics and Strenuous Labor
Drink 500 mL of water or sports drink 2 hours before vigorous exercise or work.

Continue to replace 250 mL of fluid for every 20 minutes of exertion and replace 150% of weight loss with fluid after exertion.

Acclimatization takes at least 2 weeks, and a gradual increase in activity is recommended to safely adjust to hotter environments.

Treatment of Heat Illness
If you have serious heat illness, you may feel lightheaded, nauseated, tired, anxious, and confused.

Get out of the heat into a cool, shaded place or air-conditioned building, and take off some clothing.

Put cold water or cold wet towels on your skin, and drink cold liquids.

If you are confused or lethargic or have a fever, seek medical attention immediately.
hospital admission for aggressive hydration and monitoring of renal function. Informing patients about how to avoid severe heat illness when they have mild heat illness may prevent future recurrence or more serious injury. The Patient Teaching Tips box lists information that can be given in the form of an educational handout to patients with heat illness.

### SEVERE HEAT-RELATED SYNDROMES

#### PRESENTING SIGNS AND SYMPTOMS

**HEAT EXHAUSTION**

Heat exhaustion is a systemic illness that develops as a result of heat stress and depletion of water or salt. Common symptoms are extreme thirst, dizziness, lightheadedness, fatigue, weakness, syncope, headache, malaise, and vomiting. Usually, core body temperature is normal or slightly elevated (but often lower than 40°C). Signs include tachycardia, orthostatic hypotension, tachypnea, and diaphoresis.

All patients with presumed heat exhaustion should undergo neurologic assessment to distinguish heat exhaustion from heat stroke. Heat exhaustion does not cause signs of central nervous system (CNS) dysfunction, such as delirium, ataxia, and seizures.

**HEAT STROKE**

The classic definition of heat stroke was a core body temperature higher than 40°C, CNS dysfunction, and anhydrosis. However, many cases of heat stroke have been reported in which sweating was present and the core temperature was not higher than 40°C. Therefore, the definition has been amended to a form of hyperthermia associated with a systemic inflammatory response leading to a syndrome of multiorgan dysfunction in which encephalopathy predominates.

Heat stroke resulting from failure to stay normothermic in high environmental temperatures is usually termed classic or nonexertional heat stroke, as opposed to exertional heat stroke, in which a significant component of the heat is generated by the body’s muscle tissue through strenuous work or exercise. Although both types of heat stroke are very similar, acute renal failure, rhabdomyolysis, and disseminated intravascular coagulation are more common in patients with exertional heat stroke.

The signs and symptoms of heat stroke are similar to those of heat exhaustion, except for the addition of CNS dysfunction in the form of delirium, hallucinations, ataxia, convulsions, or coma.

#### DIFFERENTIAL DIAGNOSIS AND DECISION MAKING

Many other conditions are associated with elevated core body temperature and altered mental status. Box 130.2 contains an extensive list. The EP should regard infection as a strong possibility in patients with these signs. Toxicologic, neurologic (e.g., hemorrhage, seizures), and endocrinologic (e.g., thyroid storm) causes should also be kept in mind and appropriate neuroimaging and laboratory workup ordered. Many cases of heat stroke involve victims with concomitant substance abuse, overdose, or psychiatric illnesses. Evaluation for common overdoses, medication toxicities and substances of abuse should be performed. Additionally, heat stroke often occurs in patients who have significant comorbid conditions, such as cardiac or respiratory diseases, or have another concomitant acute illness, such as infection. Therefore, it is reasonable to assess cardiac function, perform a sepsis evaluation, and evaluate for any additional conditions that the EP suspects.

#### BOX 130.2 Differential Diagnosis of Heat Stroke

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

#### TIPS AND TRICKS

Both neuroleptic malignant syndrome and heat stroke cause altered mental status and hyperthermia; unlike patients with heat stroke, however, all patients with neuroleptic malignant syndrome also have extrapyramidal rigidity. Hospital maintenance often has large fans used to dry hospital floors, which can be used to enhance evaporative cooling of a patient with heat illness.

#### DIAGNOSTIC TESTING

Heat stroke is a clinical diagnosis, but associated multiorgan dysfunction may be present. Therefore, the EP must assess the patient for the severity of dysfunction to provide appropriate supportive management. Examples of multiorgan dysfunction seen in patients with heat stroke are listed in Box 130.3.

#### TREATMENT

**PREHOSPITAL MANAGEMENT**

Morbidity and mortality are correlated with the duration and intensity of elevation in core body temperature. Therefore,
field management in which patients with possible heat stroke are identified quickly and cooling measures initiated immediately should have a significant positive effect on outcome. Measures include placing the patient in a cool, shaded environment and removing clothing. Next is either immersion in iced water (immersion) or wetting the skin with water and using a fan to aid evaporation (evaporative cooling).

Continuous monitoring and assessment of core body temperature every 5 to 10 minutes are also recommended. The ability and resources to execute these measures will vary significantly according to the setting (wilderness versus an Ironman triathlon medical tent), but even simple measures such as those recommended by the Israeli defense forces—splashing 20 to 40 mL of water on the skin and fanning the person or driving the person in an open car—effectively cool the core body temperature at a rate of 0.14°C/min.5

HOSPITAL MANAGEMENT
Some experts liken the treatment of heat stroke to that of trauma, for which there is a “golden hour” for effective intervention and stabilization of the patient. Frequently after this time, aggressive measures cannot overcome the circulatory collapse and organ failure.

The EP’s main goal is to cool the core body temperature to 38.5°C or 39°C as quickly as possible. Active cooling is not continued to normothermic temperatures to avoid the risk of overshooting and causing hypothermia. Usually, significant improvement is noted in the patient’s cardiovascular stability and mental status immediately after cooling. Methods of body cooling are defined in Table 130.3.

Debate and research continue about which cooling method is most effective and safest in treating heat stroke. Current research does not definitively answer the question of whether water immersion or evaporative cooling is significantly more effective. However, most evidence indicates that cold water immersion is superior for exertional heat stroke and that the cooler the immersion water bath, the faster the cooling.5,10,11 whereas for classic heat stroke both methods are thought to be equally effective. Additionally, if temperature can be reduced within 30 to 60 minutes, the risk for mortality is decreased.11 The choice often depends on which method can be instituted more quickly and effectively. Cold water immersion may be most useful when planned in advance for event medicine and other field applications. Evaporative cooling with the application of ice packs is a practical and effective method that can be instituted with equipment normally available in the emergency department (ED). Ice packs, wet sheets, and a fan will provide rapid cooling. Table 130.4 lists the advantages, disadvantages, and efficacy of various cooling methods.

Shivering and Vasoconstriction
Experts differ about whether shivering and vasoconstriction hinder cooling measures. Some believe that shivering and vasoconstriction require intervention, such as massage or a benzodiazepine, to prevent their negative effects on cooling. Others believe that shivering and vasoconstriction do not significantly slow the rate of cooling and may help prevent hypotension.

Hypotension
Hypotension is a common problem in patients with heat stroke and should be treated aggressively with fluid boluses, which are generally adequate. Central venous pressure of 3 to 8 mm Hg is targeted.5 If the patient’s blood pressure remains unresponsive, vasopressors are indicated. One study used isoproterenol (β-adrenergic agonist) to increase peripheral blood flow and cutaneous circulation, but this agent is used infrequently and is unlikely to result in a significant rise in blood pressure.12 An α-adrenergic agent (e.g., dopamine, which is commonly used) may be more effective in raising blood pressure but has the theoretic disadvantage of causing peripheral vasoconstriction and hence diminishing cutaneous perfusion when given in higher doses.

ADDITIONAL MANAGEMENT
Initial treatment of heat stroke is identical to that for all patients in critical condition: assessment of the ABCs (airway, breathing, circulation), cardiac monitoring, establishment of

| BOX 130.3 Organ Dysfunction Seen in Patients with Heat Stroke |
|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------||

One study used isoproterenol (β-adrenergic agonist) to increase peripheral blood flow and cutaneous circulation, but this agent is used infrequently and is unlikely to result in a significant rise in blood pressure.12 An α-adrenergic agent (e.g., dopamine, which is commonly used) may be more effective in raising blood pressure but has the theoretic disadvantage of causing peripheral vasoconstriction and hence diminishing cutaneous perfusion when given in higher doses.

ADDITIONAL MANAGEMENT
Initial treatment of heat stroke is identical to that for all patients in critical condition: assessment of the ABCs (airway, breathing, circulation), cardiac monitoring, establishment of
intravenous access and administration of normal saline or lactated Ringer solution, and liberal oxygen supplementation. Placement of a Foley catheter with temperature monitoring capability will help guide management and determine whether the cooling measures are working. Liberal use of diagnostic studies to assess organ dysfunction and other potential diagnoses is important. However, these tests must not delay the initiation of cooling measures. Empiric antibiotic treatment is appropriate when sepsis remains in the differential diagnosis.

CONSULTATIONS AND EXPECTATIONS

Admitting services consulted should include a medical or surgical intensive care unit physician. In patients with acute renal failure, a nephrologist should be involved to determine the need for dialysis. Patients with drug ingestions should be discussed with a toxicologist. Other specialty services may need to be involved depending on the individual situation, such as neurosurgery for cerebral edema and infectious diseases for suspected sepsis. Generally, the admitting service can coordinate these consultations.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

All patients with heat stroke require hospital admission. The majority will require admission to an intensive care unit or step-down unit, depending on the resources of the hospital and the severity of the illness.

Selected patients with heat stroke who respond well to ED cooling may be suitable for ward admission. Prudence would dictate consultation with an intensivist before admission to the general medical floor. Usually, these will be patients in whom heat stroke was suspected but, based on further evaluation and response to treatment, heat exhaustion seems to be a more appropriate diagnosis.

Patients with heat exhaustion who respond well to fluids, have no serious electrolyte derangements, have no evidence of mental status changes, and who are reliable with good follow-up can generally be managed as outpatients. If in doubt, overnight admission to a medical ward or an observation unit for continued hydration and reevaluation may be appropriate.
Because mental status changes and evidence of end-organ dysfunction are key components of the diagnosis and treatment of heat stroke, careful documentation of these features is important. Additionally, most patients will require documentation of bedside critical care. Patients with heat exhaustion who are able to be discharged need careful documentation of the lack of mental status changes and end-organ dysfunction, normal electrolytes, and follow-up plans and precautions. This will help justify the decision to not admit a patient with potentially serious heat-related illness.

**PATIENT TEACHING**

Patients with heat stroke will require admission. Patients with heat exhaustion who are able to be discharged will benefit from the information noted in the Patient Teaching Tips box.

**PROGNOSIS**

The prognosis of patients with heat exhaustion and more mild forms of heat illness is good, and no long-term morbidity is anticipated. The prognosis of patients with heat stroke depends on the severity, underlying comorbid conditions, and time elapsed until appropriate cooling. Mortality between 0% and 28% with appropriate treatment is reported. Survivors of exertional heatstroke that is treated aggressively rarely have long-term sequelae, whereas up to one third of survivors of classic heat stroke will have moderate to severe neurologic sequelae. Independent risk factors for mortality include hypotension (systolic blood pressure < 90 mm Hg), temperature higher than 42° C, and a Glasgow Coma Scale score lower than 12.4.

**PITFALLS**

The primary pitfall to avoid is delaying rapid cooling in any patient with suspected heat stroke. Further diagnostic and therapeutic modalities should not delay institution of cooling. Priority stabilizing actions such as airway management, vascular access, and circulatory support should occur simultaneously with cooling measures. Avoid failure to recognize that mental status abnormalities and end-organ dysfunction in a patient with heat-related illness represent heat stroke and mandate more aggressive treatment than needed for heat exhaustion.

131 Hypothermia and Frostbite

Robert L. Stephen

KEY POINTS

- Accidental (primary) hypothermia occurs when the ambient temperature outstrips a person’s ability to thermoregulate.
- Secondary hypothermia is due to an underlying medical problem that alters thermoregulation.
- Mild hypothermia is treated by passive external rewarming, moderate hypothermia by a combination of passive and active external and active internal rewarming, and severe hypothermia by active external and active internal rewarming techniques.
- For patients without a pulse or blood pressure, aggressive, invasive measures should be pursued.
- One should hesitate to declare death in a hypothermic patient. Consider rewarming to a temperature of 32° to 35° C.
- Frostbite remains a clinical diagnosis and needs to be distinguished from nonfreezing injuries (frostnip, pernio, and trench foot).
- The cornerstone of therapy is rapid rewarming in a circulating bath of heated water.
- In all aspects of care a subsequent “freeze-thaw-freeze” cycle must be avoided.
- Additional therapies involve the use of antiprostaglandins, both topical and systemic, and possibly thrombolytics.
- The full extent of frostbite injury can take weeks to become evident.

PERSPECTIVE

Accidental hypothermia is responsible for approximately 700 deaths per year in the United States. It primarily affects those least able to ward off the effects of cold weather: the very young, the very old, and the poor, disabled, pharmacologically inquisitive, environmentally adventurous, and mentally ill. Urban people are common victims. Hypothermia can occur in many latitudes, with episodes reported even in Florida. It occurs when a person’s ability to generate heat and remain warm is outstripped by the ambient temperature.

In the United States, frostbite is often a disease of the indigent, the intoxicated, the mentally ill, and winter outdoor recreation enthusiasts. For both frostbite and hypothermia the literature consists of primarily case reports, case series, and reviews.

EPIDEMIOLOGY

Accidental hypothermia is generally manifested as progression from an initial state of catecholamine release and stimulation (mild hypothermia) to one marked by a predictable slowing of metabolism and all critical body functions to the extent that patients may appear dead. The profound physiologic changes and metabolic slowing all reverse with rapid rewarming, and reports of remarkable neurologically intact survival despite hours of pulselessness and resuscitation are not infrequent. This has given rise to the adage “No one is dead until they are warm and dead.” Not surprisingly, there is little strong scientific evidence for treatment recommendations because trials cannot be conducted. The medical literature is composed mostly of animal experiments, case reports and series, and retrospective reviews. Still, rational approaches can be inferred from the extant literature for this uncommon but serious problem (Table 131.1).

Frostbite is a freezing injury to soft tissues secondary to cold exposure and results in loss of circulation to and therefore viability of the affected area. The extremities, nose, ears, and male genitalia are the most commonly affected areas.

HYPOTHERMIA

PATHOPHYSIOLOGY

MECHANISMS OF HEAT LOSS

The mechanisms of heat loss are as follows:

- Radiation of heat occurs when the ambient temperature is less than body temperature and heat is lost directly to the environment via electromagnetic radiation.
- Conduction is heat transfer from one (warmer) solid to another (cooler) when they are in contact.
Convection is loss of heat from a surface to a (usually moving) gas or fluid, typically air or water. It can be considered an adjunct to conduction.

Evaporation causes heat loss through the energy required to vaporize water (i.e., sweat).

As a person cools, a fairly predictable procession of pathophysiologic changes occurs, as seen in Table 131.2 and Figure 131.1.

PRESENTING SIGNS AND SYMPTOMS

Patients with mild hypothermia are awake, occasionally drowsy, uncomfortable, and shivering. They simply need insulation (blanket), dry clothes, and food. They will recover completely and can be discharged when normothermic and feeling better.

Patients with moderate hypothermia are generally confused and lethargic, often have slurred speech, and are typically not shivering. They require more energetic rewarming measures, including heated blankets, resistive and hot air blankets (Bair Hugger), and close monitoring, including core temperature. Though strictly considered active internal rewarming, the use of heated, humidified oxygen and warmed intravenous (IV) fluids is reasonable in this situation. Patients whose hypothermia responds to these measures may be discharged when normothermic, awake, alert, and ambulatory. Patients with severe hypothermia require prompt intervention, close monitoring, and potentially aggressive, invasive rewarming therapies.

It is of the utmost importance to learn the circumstances that led to the patient becoming hypothermic. The possibility of a verify drug overdose, trauma, infection, drowning, or decompensated comorbid conditions—to name but a few examples—must be considered, sought, and treated along with the hypothermia.

The critical element of the diagnosis of hypothermia is accurate measurement of core temperature. Several methods exist, all of which have potential drawbacks (Table 131.3). Laboratory and physiologic changes are correlated with the temperature. For example, a normal hematocrit value in a

| Table 131.1 Definitions of Hypothermia |

severely hypothermic patient should prompt concern for hemorrhage because the hematocrit should rise in a predictable fashion with ever-lowering temperature. Alternatively, arterial blood gas values should be interpreted as though the patient is normothermic (the alpha-stat method) and not corrected for the actual core temperature (the pH-stat method). Evaluation for infection, metabolic derangement, and cardiac, neurologic, renal, and other organ system abnormalities is important because comorbid conditions are common as a cause, a consequence, or coincidence of hypothermia.

### MILD HYPOTHERMIA

Patients with mild hypothermia may be treated with passive external rewarming. Such treatment, which consists of the use of blankets, dry clothes, ambient warmth, oral hydration, and energy substrate (food), produces a rewarming rate of about 0.5°C to 1°C per hour. The approach uses the patient's inherent ability to keep warm, primarily through shivering, and insulation.

### MODERATE HYPOTHERMIA

Patients with moderate hypothermia should undergo active external rewarming. Heat is actively supplied to the body via electric blankets, forced-air blankets, and space heaters. This method achieves rewarming rates of about 1°C to 2°C per hour.

### SEVERE HYPOTHERMIA

Active internal rewarming is needed for patients with moderate and severe hypothermia. Actions are directed toward heating the core preferentially over the periphery. This goal is accomplished via methods of variable invasiveness and complexity, as follows:

- Heated, humidified oxygen (40°C to 45°C) administered via face mask or endotracheal tube; it primarily serves to prevent additional heat loss.
- Administration of heated IV fluids (40°C to 42°C) adds negligible heat overall but does aid in preventing further heat loss.
- Gastric or bladder lavage (or both) via nasogastric tube and Foley catheter is relatively easily accomplished; however, the small volume of these cavities limits the effectiveness of these modalities.
- Peritoneal lavage with prepackaged dialysate or standard crystalloid fluids heated to about 45°C. This method is quicker if two catheters, one for afferent flow and one for efferent flow, are used. Rewarming rates average 2°C to 3°C per hour.
- Closed thoracic cavity lavage (pleural lavage) of the left hemithorax is done with two 36-French thoracostomy tubes and isotonic fluid heated to about 42°C. Large volumes are required. The afferent tube is placed in the second intercostal space (ICS) in the midclavicular line. The efferent tube is placed in the usual location, the fourth or fifth ICS in the

### TREATMENT

#### MILD HYPOTHERMIA

Patients with mild hypothermia may be treated with passive external rewarming. Such treatment, which consists of the use of blankets, dry clothes, ambient warmth, oral hydration, and energy substrate (food), produces a rewarming rate of about 0.5°C to 1°C per hour. The approach uses the patient's inherent ability to keep warm, primarily through shivering, and insulation.

#### MODERATE HYPOTHERMIA

Patients with moderate hypothermia should undergo active external rewarming. Heat is actively supplied to the body via electric blankets, forced-air blankets, and space heaters. This method achieves rewarming rates of about 1°C to 2°C per hour.

#### SEVERE HYPOTHERMIA

Active internal rewarming is needed for patients with moderate and severe hypothermia. Actions are directed toward heating the core preferentially over the periphery. This goal is accomplished via methods of variable invasiveness and complexity, as follows:

- Heated, humidified oxygen (40°C to 45°C) administered via face mask or endotracheal tube; it primarily serves to prevent additional heat loss.
- Administration of heated IV fluids (40°C to 42°C) adds negligible heat overall but does aid in preventing further heat loss.
- Gastric or bladder lavage (or both) via nasogastric tube and Foley catheter is relatively easily accomplished; however, the small volume of these cavities limits the effectiveness of these modalities.
- Peritoneal lavage with prepackaged dialysate or standard crystalloid fluids heated to about 45°C. This method is quicker if two catheters, one for afferent flow and one for efferent flow, are used. Rewarming rates average 2°C to 3°C per hour.
- Closed thoracic cavity lavage (pleural lavage) of the left hemithorax is done with two 36-French thoracostomy tubes and isotonic fluid heated to about 42°C. Large volumes are required. The afferent tube is placed in the second intercostal space (ICS) in the midclavicular line. The efferent tube is placed in the usual location, the fourth or fifth ICS in the
midaxillary line. Fluid is literally poured in by hand, infused with a large (60-mL) syringe, or administered directly with a rapid infuser (the hub of the rapid infuser fits snugly into the bore of a 36-French chest tube). Rewarming rates average about 3° C per hour.1,8

• Left thoracotomy with mediastinal irrigation and internal cardiac massage is quite invasive with high attendant morbidity. It is very effective and self-explanatory and has rewarming rates as high as 5° C to 6° C per hour.7,8

• Cardiopulmonary bypass (CPB) is the definitive method for rewarming. It is rapid, with rewarming rates of 9° C per hour or higher achieved, and supports blood pressure; however, CPB also requires specialized equipment and personnel that are not readily available in most hospitals.9,10

The use of medications, particularly cardioactive medications and vasopressors, is theoretically unappealing and thought to be potentially dangerous in a patient with a core temperature lower than 30° C, primarily because of decreased metabolism, which can lead to toxic levels. Similarly, defibrillation is less likely to be effective at temperatures lower than 30° C. However, citing the solely theoretic basis of these concerns, the 2010 American Heart Association guidelines now state that in patients with persistent ventricular fibrillation or tachycardia after a single shock it may be “reasonable to perform further defibrillation attempts according to the standard BLS [basic life support] algorithm concurrent with rewarming strategies.” Furthermore, regarding medication administration “it may be reasonable to consider administration of a vasopressor during cardiac arrest according to the standard ACLS [advanced cardiac life support] algorithm concurrent with rewarming strategies.” It is clear that very little is known about the utility of defibrillation and administration of vasoactive medications in patients with hypothermic cardiac arrest. Providers will have to decide each case on an individual basis and be guided by any response to the therapy used.

The phenomenon of core temperature afterdrop refers to the observation that a patient’s temperature can fall after rewarming efforts have begun. It is believed to be due to a combination of temperature equilibration and return of cold blood from the periphery to the patient’s core as perfusion is restored and strengthened. The clinical importance of core temperature afterdrop is keenly contested, and no consistent recommendations can be made regarding it. Certainly, attempts to rapidly rewarmin a patient should not be delayed for fear of this consequence.

**NEXT STEPS IN CARE**

Patients with mild hypothermia and (most) patients with moderate hypothermia can be treated in the emergency department and released when normothermic. This statement relies on the assumption that no other complicating social or medical problems are present that must be addressed. All patients with severe hypothermia should be admitted to the hospital, usually to an intensive care unit. Successful revival of these patients will require considerable time and resources.

Clear, universally accepted criteria on declaration of death in hypothermic patients are lacking, beyond the obvious recommendations regarding terminal injuries, rigidity that precludes chest compressions, and physical blockage of the mouth or nose by ice.

Numerous case reports have described neurologically intact survival after prolonged, severe hypothermia with cardiac arrest.7,12 A serum potassium level higher than 10 mmol/L has been postulated to be a marker of irreversible cell and therefore patient death14; however, another case report has called this approach into question.19 Pronouncement of death in a severely hypothermic patient should be made with reluctance until the patient’s core temperature has been warmed to higher than 30° C to 32° C and signs of life remain absent.

A reasonable approach to the hypothermic patient is presented in Figure 131.2.

**FROSTBITE**

**PATHOPHYSIOLOGY**

Frostbite is a freezing injury to tissues. During this process it is believed that deposits of ice crystals causing interstitial, cellular, and vascular endothelial cell damage are one part of the pathophysiologic process.15 The vascular endothelial damage results in activation of the clotting cascade with resulting thrombosis, which leads to hypoperfusion, ischemia, and eventually tissue necrosis. The prominence of the clotting that can cause vascular occlusion can be seen on angiography and is the basis for the concept of treating selected patients with thrombolysis.

**PRESENTING SIGNS AND SYMPTOMS**

The classic victim of frostbite has either a dusky or a white affected area that is brawny to solid in texture, insensate, and without capillary refill. Variations are time dependent, and patients seen in delayed fashion may have blisters that are either hemorrhagic or clear and even some tissue loss or frank necrosis already evident. Classification systems exist for frostbite, but they are controversial and are also problematic for the emergency physician because the initial clinical appearance can be misleading and it takes time for the full extent of the damage to become clear. It is simpler and more realistic to start to treat the affected part and consult surgeons for ongoing wound care and treatment (Fig. 131.3).

**TREATMENT**

Frostbite is a clinical diagnosis. Other cold-related tissue injuries to be considered are frostnip, pernio (chilblains), and trench foot. These injuries, however, are nonfreezing ones, in contrast to frostbite.
**PREHOSPITAL MANAGEMENT**

Treatment of frostbite in the field consists of the application of dry sterile dressings to separate the involved digits and elevation of the affected extremity. Avoid rewarming with dry heat, such as with fires or heaters, and also assiduously prevent further cold injury. Rubbing the affected part with snow is soundly condemned. It is paramount to avoid a freeze-thaw-freeze cycle, which worsens the tissue damage.

**HOSPITAL MANAGEMENT**

Once the patient is in the hospital, the mainstay of treatment is rapid rewarming with a circulating bath of water heated to 40°C to 42°C for 10 to 30 minutes until the involved area is erythematous and pliable. Because rewarming is extraordinarily painful, liberal use of parenteral analgesics is usually necessary. Clear, large blisters should generally be débrided, but hemorrhagic ones should be left intact (their presence implies much deeper damage, and desiccation of the area is a concern). Débridement removes fluid that is rich in thromboxanes and prostaglandins, which are thought to be destructive to tissue. Aloe vera may be applied topically every 6 hours and the wounds bandaged.

Prophylactic antibiotics are controversial. Penicillin G has been advocated. Additionally, ibuprofen, 400 mg by mouth twice daily, is recommended in an attempt to interrupt the arachidonic acid cascade. Both catheter-directed intraarterial and systemic thrombolytic therapies have been used with impressive success in preventing amputations (Figs. 131.4 and 131.5). This novel therapy holds considerable promise but does have several limitations, including restriction to patients initially seen within 24 hours of the injury and risk for bleeding.

Most recently, a small, randomized trial of frostbite therapies showed remarkable success with intravenous iloprost, a prostacyclin (no digit amputations), over an IV nonsteroidal antiinflammatory drug (≈40% digit amputation rate) or recombinant tissue plasminogen activator plus iloprost (≈3% digit amputation rate). Whether this promising success can be repeated and confirmed elsewhere remains to be seen.

Early surgical management is not indicated for frostbite because of the difficulty of ascertaining the full extent of the...
Frostnip is a superficial freezing injury that appears pale and can be associated with discomfort. It resolves with rewarming without sequelae.

Pernio (chilblains) is due to repeated, intermittent exposure to wet, nonfreezing temperatures. Localized edema, erythema, nodules, plaques, cyanosis, and possibly vesicles and ulcerations appear up to 12 hours after exposure. Burning paresthesias and itching may be present, and rewarming can result in the formation of bluish nodules. Care is supportive and consists of rewarming, bandaging, and elevation. Nifedipine, pentoxifylline, or limaprost has been advocated as potential therapy. Topical and oral corticosteroids may be useful.

Trench foot is direct soft tissue injury secondary to prolonged immersion in cold water. It develops slowly, but the damage, though initially reversible, may become permanent if not treated. Early in the course, paresthesias develop in a pale, mottled, insensate, and possibly pulseless foot. It becomes hyperemic after rewarming, with return of sensation (proximal more than distal) and severe burning pain. Edema and blisters can form, and in severe cases, tissue sloughing and gangrene can develop. Prevention is paramount, but when it does occur, trench foot is treated supportively much like chilblains.
tissue damage initially. Typically, the affected area is left to mummify and essentially autoamputate before the formal procedure is carried out. Some newer imaging modalities, such as nuclear scanning and magnetic resonance angiography, may be able to shorten the time to definitive surgery by delineating viable tissue earlier than possible with simple observation.

**NEXT STEPS IN CARE**

Because of the severity of frostbite, the need for daily hydrotherapy and wound care, and the often tenuous social circumstance of those afflicted, most patients with frostbite should be admitted to the hospital under the care of a physician skilled in treating this illness. In many cases, burn centers are an excellent option.

132 Lightning and Electrical Injuries
Christopher B. Colwell

KEY POINTS

- In high-voltage electrical injuries, the internal damage that the victim has suffered can be significantly greater than the external damage or surface injury indicates.
- Fixed, dilated pupils are not a reliable indicator of brain death in the victim of a lightning strike.
- Oral burns in children can represent electrical injury from chewing on electrical wires.
- Victims in cardiac arrest may respond quite well to defibrillation, so these patients should receive highest priority for treatment at the scene.
- Victims of electrical injuries who have any symptoms are at high risk for compartment syndrome.
- Blunt trauma can occur in up to one third of victims of lightning or high-voltage electrical injuries.

EPIDEMIOLOGY

A strike of lightning is one of the most common environmental causes of sudden cardiac death and is responsible for between 50 and 300 deaths annually in the United States. Cloud-to-ground lightning strikes, the most destructive form of lightning, occur approximately 30 million times each year, most often in Florida and along the southeastern coast of the Gulf of Mexico. Lightning has struck more than 10 miles away from the rain of a thunderstorm, so the danger may not always be obvious or apparent. Electrical injuries can be equally devastating. The spectrum of injuries from both can range dramatically from minor, localized injuries to death.

Although lightning injury may be one of the most common injuries caused by natural phenomena, its incidence has not been tracked accurately. The incidence is higher in males and in people between 20 and 44 years of age, three of every four occurred in the South or Midwest, and one in four was work related. Sport-, wilderness-, and travel-related activities also place people at higher risk for lightning injuries.

Electrical injuries tend to occur in patients in three distinct age groups. The first group is toddlers who encounter household electrical sockets, cords, and appliances. The second is adolescents who engage in risky behavior. The third group comprises adults who work with electricity. Electrical burns account for between 3% and 7% of admissions to burn centers in the United States each year, many of which are occupational injuries. The annual occupational death rate from electrocution is 1 per 100,000; this type of death occurs more frequently in utility workers, miners, and construction workers.

PATHOPHYSIOLOGY

Definitions that should be familiar to those caring for patients with electrical injuries are listed in Box 132.1. Electrical current is the movement of electrical charge from one location to another. Current strength is expressed in amperes. Materials that allow electrical current to flow easily (low resistance) are referred to as conductors. Materials that do not allow flow of electrical current are called insulators.

All body tissues conduct electricity to some extent. Tissues with high fluid content conduct better than those with lower fluid content. Nerves tend to offer the least resistance, whereas bones offer the most. Table 132.1 lists body tissues according to level of resistance. Skin resistance can vary substantially, with wet skin having the lowest resistance. Factors determining the severity of the injury caused by the electrical current are listed in Box 132.2.

Any electrical charge greater than 1000 V is generally considered high voltage, although some authorities have argued that the risk for significant injury increases with charges exceeding 600 V. Typical household circuits in the United States are 110 V, with bigger appliances operating on 220-V circuits. Power lines in residential areas can have more than 7000 V.

Electricity causes injury in several ways, as listed in Box 132.3. As current passes through the body, the tissues through which it passes are heated, and significant damage can occur. The emergency physician (EP) must be aware of the potential for internal damage when caring for a victim of electrical injury; not all patients with significant internal injuries display significant external damage. Arc burns result from an electrical source through the air and can cause significant damage. Temperatures can reach 2500° C, which can ignite clothes or nearby material and cause thermal injuries. Flash burns occur when current strikes the body but does not penetrate the skin.
Lightning delivers high-voltage direct current that tends to flow over the body rather than enter it. This event, often referred to as flashover, is one explanation for how people are able to sometimes survive exposure to such high voltage. Lightning current can also enter the victim and cause significant damage, particularly to the cardiac, respiratory, and neurologic systems. Blunt injury has been reported in up to one third of lightning victims as a result of both the direct force of the strike and rapid expansion of the surrounding air, which often causes the victim to fall or be struck by flying debris. Lightning can also cause thermal injury (burns) by hot steam produced from surrounding moisture or by metal objects heated by the electricity. Box 132.4 lists the mechanisms of injury from lightning strikes.

**ANATOMY**

Cardiac arrest is the primary cause of immediate death after both electrical and lightning injuries. Electrical injuries can result in virtually any type of dysrhythmia, although rhythm disturbances are unlikely if the exposure is to less than 120 V and water is not involved. Lighting also causes a variety of cardiac rhythm disturbances. Acute myocardial infarction is uncommon with both electrical and lightning injuries. Other cardiac sequelae of lightning injuries have been described and include cardiogenic shock and Takotsubo cardiomyopathy.

The head is a common point of contact for high-voltage injuries, and skull and cervical spine injuries occur as a result of blunt trauma from lightning and electrical injuries. Eye and ear injuries can both occur with electrical or lightning injuries, primarily in the form of burns. Injury to the extremities occurs with both lightning and electrical injuries, but high-voltage electrical injuries are far more likely to result in compartment syndromes.

Kidney damage or even acute renal failure can develop as a result of myoglobinemia, although this condition often responds well to fluid resuscitation. Gastrointestinal tract dysfunction, including bleeding and ulcer formation, has been described as well.

Environmental circumstances
Pathway of the current

**BOX 132.3 Mechanisms of Electrical Injury**

Direct tissue damage (entry and exit sites)
Internal thermal heating
Induced muscle contraction
Flash burns
Arc burns
Blunt trauma

**BOX 132.4 Mechanisms of Injury from Lightning Strikes**

Direct strike
Contact strike: Lightning strikes an object that the victim is touching
Side flash: Lightning strikes a nearby object, and electrical current then traverses the air to strike the victim (can involve multiple victims)
Ground strike: Lightning hits the ground and is transferred to a person standing near the site of the strike. If there is a difference in potential between the legs of the victim, lightning can enter one leg and exit the other and thereby result in temporarily paretic, cold, insensate, and pulless legs (keraunoparalysis)
**SECTION XIII  ENVIRONMENTAL DISORDERS**

**PRESENTING SIGNS AND SYMPTOMS**

Victims of high-voltage electrical injury typically have significant burns with a very dramatic appearance. Victims of low-voltage electrical injury or lightning injury may appear quite well. The most severe injuries are generally those affecting the cardiovascular and neurologic systems, and cardiac arrest is the most common cause of immediate death and is generally manifested as asystole (direct current) or ventricular fibrillation (alternating current).

Other than cardiac arrest, the most significant obvious injuries caused by exposure to electricity are usually burns, which are frequently most severe at the source of the electricity, as well as at the exit point, which is commonly a ground contact point (usually the heel). The EP should assume significant underlying damage in all patients with electrical or lightning injuries. Lightning contact is generally instantaneous and leads to flashover burns that are more often superficial and minor. Extensive burns and deeper injury are more common with high-voltage electrical injuries, frequently because of more prolonged contact.

The neurologic effects of electrical and lightning injuries can be immediate (which are often transient) or delayed (which last for a longer period and are more likely to be progressive). The prognosis is usually better for patients with more immediate symptoms than for those with delayed manifestations. Initial findings include altered mental status, which is frequently transient but can range from slightly agitated to comatose. As current passes through the skull, heat-induced coagulation can occur and result in subdural and epidural hematomas, as well as intraventricular hemorrhage. Weakness and paresthesias of the extremities also occur and are more common in the lower than the upper extremities. Seizures have likewise been described.

Up to two thirds of victims of lightning strikes experience keraunoparalysis, a temporary paralysis specific to lightning injuries that is characterized by blue, mottled, and pulseless extremities (lower more commonly than upper). Permanent paresthesias can result but are unusual.

Blood is a good conductor of electricity, and vascular damage from electrical and lightning injuries has been well described. Thrombosis, hemorrhage, and ischemia can occur as a result of direct damage to vessel walls, vasospasm, or burns. Small arteries to muscle are at particular risk.

Skin findings include feathering burns, flash burns, contact burns, punctate burns, blistering, and linear streaking. A specific type of burn associated with electrical injury is referred to as a “kissing burn,” which occurs at the flexor creases of the knees, elbows, and axilla. Kissing burns indicate extensive underlying damage, so EPs must be sure to look at the flexor surfaces for lightning or electrical injury when evaluating patients who are victims.

Contact with electrical current tends to produce burns that result in discolored (often gray or yellow), painless, depressed, punctate areas of the skin. It is important to recognize that tissue damage under these burns can be massive.

Feathering burns (also known as Lichtenberg figures) are specific to lightning injuries and result from electron showers induced by the lightning that make a fern pattern on the skin. No permanent damage to the skin occurs, and no specific therapy is required. Punctate burns are full-thickness burns that look like multiple small burns from a cigarette. Deep burns are rare with lightning injuries.

Oral burns in children often represent electrical injury from chewing or sucking on electrical wires. These injuries are particularly worrisome because of the possibility of delayed bleeding, which can be massive from the labial artery when the eschar separates, sometimes 5 days or more after the injury.

High-voltage electrical injuries and lightning injuries can both result in damage to the eyes and ears. Electrical injury is more likely to injure the eye if the exposure involves the head or neck, and such injuries include corneal burns, retinal detachment, and intraocular hemorrhage. Delayed cataract formation has been described in up to 6% of patients. Lightning injuries can also cause uveitis, iridocyclitis, mydriasis, anisocoria, or Horner syndrome. It is for this reason that fixed, dilated pupils are not a reliable indicator of brain death in lightning strike victims. Damage to the ear is common with lightning injuries; rupture of the tympanic membrane is the most common finding, and the symptoms are generally transient hearing loss and vertigo.

Blunt trauma is common in the setting of electrical and lightning injuries, either from being thrown back from the source or from incidents resulting from the exposure, such as falls. Long-bone fractures, dislocations, and solid internal organ injury have been associated with both electrical and lightning injuries.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Electrical injuries are generally more obvious than lightning injuries. With the exception of bathtub electrical injuries, where burns may not be apparent, a good history and thorough physical examination usually reveal the cause of the electrical injuries, ideally including the type of current, voltage, duration of contact, and symptoms immediately after the attack. Lightning injuries are not always as evident (lightning can strike when no rain or snow is present and even on mostly sunny days) and may be manifested as cardiac arrest, altered mental status, or paralysis. Recognition of classic patterns of lightning injury, such as feathering, may be the only way to initially distinguish these injuries from other causes of cardiac arrest, altered mentation, or acute neurologic injury. Differential diagnoses in which a history of lightning injury or high-voltage electrical injury is not obvious are listed in Box 132.5.

---

**FACTS AND FORMULAS**

Ohm’s law: $V = I \times R$

where $V =$ potential (in volts); $R =$ resistance (in ohms); $I =$ current (an amperes)

$P = I^2Rt$

where $P =$ heat (in joules); $I =$ current (in amperes); $R =$ resistance (in ohms); $t =$ time (in seconds)
CHAPTER 132  LIGHTNING AND ELECTRICAL INJURIES

Tomography of the head should be performed in anyone with altered mental status or a significant headache given the risk for intracranial bleeding from either direct contact (particularly lightning) or the resulting head trauma. Cervical spine films should be obtained for patients with altered mental status or significant cranial injuries, including burns. A pregnancy test should be performed on all women of childbearing age.

TREATMENT

Prehospital providers must be particularly vigilant about scene safety. With electrical injuries involving a discrete electrical source other than intact electrical outlets, the power must be turned off before the victim is approached. Any provider at the scene of a lightning injury must remember that lightning can strike in the same place twice. In addition, both electrical injuries and lightning injuries should be considered to pose a high risk for concomitant blunt trauma, and spinal immobilization should be initiated unless clearly not indicated.

Lightning injuries are an exception to the general rule that in mass casualty and disaster situations, people in cardiac arrest should be categorized or tagged as “black” (expectant or dead) and receive the lowest priority for treatment on the scene. Unlike the situation in most other mass casualty situations, cardiac arrest in the setting of lighting or electrical injury may be quickly reversed with defibrillation. Triage for multiple victims of lightning injuries at one scene should concentrate on those in cardiorespiratory arrest, and immediate treatment of those who are breathing can be reasonably delayed when necessary. Regardless of whether there are multiple casualties, victims of lightning injuries who are in cardiac arrest should be aggressively resuscitated whenever possible because evidence suggests that success rates are higher than in patients in cardiac arrest from other causes, even when the interval before resuscitation is prolonged.5

Rhabdomyolysis can be treated effectively by aggressive fluid administration, with the goal of urine output greater than 1 mL/kg/hr. Formulas used to determine fluid resuscitation in burn victims cannot be used for electrical injuries. Fluid resuscitation in patients with lightning-related injuries does

Diagnosis and Treatment of Lightning Injury

Intracranial disease:
- Cerebrovascular accident
- Intracranial hemorrhage
Seizure disorder
Closed head injury
Spinal trauma
Encephalopathy
Primary cardiac dysrhythmia
Toxic ingestion

RED FLAGS

Do not underestimate the potential for significant underlying tissue damage, particularly with high-voltage electrical injury, even when the skin findings appear minor.

Traditional rules of triage do not apply to lightning victims. In this situation, care should be focused on rather than withheld from those in cardiopulmonary arrest.

Do not miss compartment syndrome, particularly with high-voltage electrical injury.

Consider the potential for rhabdomyolysis in all victims of high-voltage electrical injury, and provide adequate hydration. Beware of overaggressive hydration in lightning victims.

Admit patients for cardiac monitoring who have lost consciousness, have any evidence of cardiac instability or dysrhythmia, or have a transthoracic injury pattern.

Ensure good follow-up and provide careful instructions for the parents of children with oral burns, who are at risk for both cosmetic defects and delayed labial artery bleeding.

Remember the risk for blunt trauma in victims of high-voltage electricity and lightning.

Patients with neurologic complaints or deficits are at risk for permanent neurologic sequelae, particularly when the symptoms are delayed.

Remember to evaluate for tetanus immunization status and update as needed.

Cardiac monitoring and electrocardiography are indicated for all but the most benign electrical injuries and for virtually all lightning injuries. QT prolongation is a common finding. Complete blood counts are usually recommended, but their results should be normal. Abnormalities are more likely to be found when checking electrolyte, blood urea nitrogen, and creatinine values. Urinalysis should be performed to look for evidence of myoglobinuria, the presence of which indicates rhabdomyolysis. The serum creatine kinase value may also point to rhabdomyolysis. Acute myocardial infarction is rare with either lightning or electrical injuries. Computed
not have to be very aggressive unless they are hemodynamically compromised. Fluid overload is a common iatrogenic complication in patients with lightning injuries.

Fasciotomy must be considered in patients with extremity burns from high-voltage electrical injuries in which compartment syndrome is a concern. Circumferential burns are more likely to result in compartment syndrome.

Tetanus boosters should be administered to patients whose immunization status is not up to date and even to those whose immunization status is current if they have significant muscle damage or contamination of the wounds because electrical wounds are especially prone to tetanus.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Asymptomatic patients with normal physical findings who were victims of low-voltage electrical injury can be discharged safely without significant evaluation or observation. Patients with low-voltage injuries for whom risks are higher include those whose skin was wet during the injury, those with tetany, and those in whom the current traversed the thorax. Patients with mild symptoms, normal electrocardiographic findings, and no evidence of myoglobinuria can be discharged after a period of observation (generally 4 to 6 hours, although no research has confirmed this interval) and with recommendation for outpatient follow-up.

Any patient who experienced cardiac or respiratory arrest or clear loss of consciousness or has abnormal or changed electrocardiographic findings, hypoxia, chest pain, dysrhythmia observed by a medical care provider, or serious concomitant injury should be admitted.

**DOCUMENTATION**

A large percentage of electrical injuries involve legal claims of some sort (e.g., worker's compensation, manufacturers), so the medical record should be complete with particular emphasis on the available history, physical findings, and treatment rendered. The record should include the following:

- Whether loss of consciousness was involved
- Voltage of the exposure if known
- Initial symptoms
- Skin findings
- Electrocardiographic findings
- Condition and symptoms at discharge

Dysbarisms, Dive Injuries, and Decompression Illness

Heather Murphy-Lavoie and Tracy Leigh LeGros

KEY POINTS

- Decompression illness describes diving-related injuries, including decompression sickness and arterial gas embolism.
- Any neurologic symptoms that occur in a diver immediately or soon after resurfacing are highly suspicious for arterial gas embolism and require urgent medical attention.
- A thorough neurologic examination is crucial with any suspicion of decompression illness.
- Dive injuries are best differentiated into the following categories: disorders of descent, disorders at depth, disorders of ascent, and disorders that occur after resurfacing.
- Decompression illness is treated on the scene by rapid implementation of high-flow oxygen and intravenous hydration; definitive treatment is recompression with hyperbaric oxygen therapy.
- One should delay flying after diving for at least 12 hours following a single no-decompression dive and at least 24 hours for dives involving decompression stops.
- Consultation with a diving physician or the Divers Alert Network (or both) is needed for a patient with any symptoms associated with recent diving.

PATHOPHYSIOLOGY

Dysbarism refers to the effects of variations in ambient (surrounding) pressure on the body. Hypobaric (low-pressure) exposure, such as that experienced by climbers, pilots, and astronauts, can result in symptoms and injuries similar to those found in divers with DCI who are exposed to high pressure while at depth. Decompression injuries during high-pressure (hyperbaric) exposure are far more common.

DIVING PHYSIOLOGY

Evaluation of a diver with a water-associated injury requires a basic understanding of diving physiology and the physics of pressure and gases. Different gases have different properties at different depths, which allows gases to be used alone or in combination for different types of diving. The gases of most interest are air, oxygen, nitrogen, helium, and occasionally argon. Deep diving (past 180 feet of sea water [fsw]) often requires helium-oxygen combinations (heliox) to mitigate the effects of nitrogen narcosis (discussed later). Moreover, enriched nitrogen-oxygen combinations (nitrox) may be used to reduce obligations for decompression stops, which is the time spent at more shallow depths to help divers offload the nitrogen built up in the body before exiting a dive.

In general, most recreational divers breathe compressed air and use a self-contained underwater breathing apparatus (SCUBA) when diving to depths of less than 135 fsw. Nitrogen represents about 78% of the gas inhaled with compressed air diving. During diving, hydrostatic pressure “pushes” nitrogen into tissues; nitrogen (an inert gas) then becomes dissolved in plasma and permeates tissues. While at depth, gases remain in solution, and most divers experience minimal difficulty. The deeper that divers travel and the longer that they remain at depth, the more saturated the blood and tissues.

EPIDEMIOLOGY

Dysbarisms refer to the pathophysiologic effects of changes in ambient (surrounding) pressure on the body. Decompression illness (DCI) includes decompression sickness (DCS or “the bends”) and arterial gas embolism (AGE). DCI occurs during or after ascent (decompression) when dissolved gases come out of solution, form bubbles, and then become lodged in various tissues (instead of being filtered by the lungs). Diagnosis of DCI in the emergency department (ED) is vital because delayed treatment or missed cases can have permanent sequelae (Box 133.1).

With the advent of “extreme sports” that involve water contact, sport diving, and the increasing number of people engaging in breath-hold diving, a sharp increase in diving injuries has been seen in EDs (Box 133.2). Deaths from breath-hold diving alone have almost doubled in the last 5 years, thus illustrating the potential for injury associated with this form of diving. With acute DCI, rapid assessment and treatment are the foundation of management. Three keys to successful ED treatment are having a high index of suspicion (DCI may have nonspecific findings), performing a thorough neurologic examination, and obtaining hyperbaric medicine consultation when DCI is suspected.
become with nitrogen (or other inspired inert gases). One of the tenets of diving is to ascend slowly when resurfacing. Doing so allows the dissolved (inert) gases to escape the tissues slowly and be cleared via normal respiration. If a person ascends to the surface too quickly, the dissolved gases come out of solution and form bubbles in tissues or within the vasculature. When these bubbles are not cleared by the lungs (“blown off”) they can embolize and cause downstream injury or they can cause local damage at the site of formation (autochthonous bubbles). When bubbles cause symptoms, the disorder is called DCI. Depending on the size, number, and location of the bubbles, DCI has a wide range of manifestations, from pain (most common symptom), numbness, and fatigue to severe neurologic symptoms such as seizure, paralysis, and loss of consciousness (LOC).

**Bubble Physiology**
Knowledge of bubble mechanics and the effects of bubbles in various tissues is critical to understanding the pathophysiology and treatment of DCI. Venous bubbles are not usually problematic because the lungs can filter large gas loads. Bubbles have damaging effects when they remain within tissues or embolize. Bubbles can pass from the venous circulation to the arterial circulation via a right-to-left shunt (patent foramen ovale or arteriovenous malformation). Bubbles can grow from “nucleation sites” within body tissues, such as the joint spaces, tendon sheaths, periarticular sheaths, and peripheral nerves. Once inside these areas, bubbles can act as emboli and block perfusion of distal tissues or act as foreign bodies with resultant vascular damage through activation of the inflammatory and clotting cascades. Interestingly, scientists are now evaluating a possible biologic marker of DCI. As gas emboli within the circulation induce decompression stress, endothelial cells release microparticles in response to cellular activation or cell death. These microparticles may, in the future, reflect a biologic marker of decompression stress that can be used to gauge the extent of disease, efficacy of treatment, or prophylaxis.

**Principles of Gas Laws and Dysbarism**
An understanding of the pertinent diving gas laws, units of measurement, abbreviations, and mathematical conversions helps facilitate the treatment and disposition of dive-injured patients. At sea level, the pressure of the atmosphere on the body (ambient pressure) is 760 mm Hg, which equals 1 atm. The term for the absolute pressure on a diver at sea level is called atmospheres absolute (ATA), and it represents the total sum of the pressure on a diver. Therefore, at sea level, a dive computer gauge reads zero, but sea level also represents one surrounding atmosphere of pressure (1 ATA). This knowledge helps the physician better comprehend the circumstances surrounding a dive injury. Although there are a large number of gas laws, the two that are the most important in diving medicine are Boyle’s law and Dalton’s law.

**Boyle’s Law**
Boyle’s law aids in understanding why a diver needs to exhale while ascending from depth. According to Boyle’s law, the volume of a quantity of gas \(V\) varies inversely with the pressure on that gas \(P\) if it is kept at a constant temperature. It is often represented by the following formula:

\[
P_1V_1 = P_2V_2
\]

where the subscripts 1 and 2 indicate two different combinations of pressure and volume; in other words, the product of pressure and volume will always remain a constant.

Usually, as a diver descends deeper, the surrounding pressure increases in linear fashion. Water pressure at the surface is referenced as 1 ATA. In general, for every 33 ftw that the diver descends, there is an increase in pressure of 1 ATA. Therefore, a descent to 33 ftw would equal 1 ATA, a descent to 66 ftw would equal 2 ATA, and so on. Furthermore, for the first 33 ftw descended, the volume of gas present is reduced by half the original amount of gas at the surface. At 66 ftw, the volume is one third the original volume. The greatest changes in volume occur closest to the water surface and represent a significant vulnerability to injury (Fig. 133.1).

**Dalton’s Law**
Dalton’s law of partial pressures is critical to understanding the mechanisms for DCS, nitrogen narcosis, and oxygen toxicity. It is represented by the formula

\[
P_{\text{total}} = P_1 + P_2 + P_3
\]
Barotrauma is sustained from failure to equalize the pressure of an air-containing space with that of the surrounding environment. The most common examples of barotrauma occur during air travel and scuba diving. Barotrauma occurs only in gas-containing (compressible) body spaces. More than 95% of the body is composed of water (incompressible). Typical gas-filled spaces include the sinuses, middle and inner ears, air-filled areas within carious or filled teeth, and hollow viscous organs such as the intestines and lungs. Barotrauma incurred during descent is called a “squeeze.” Barotrauma.
incurred during ascent is called a “reverse squeeze,” “reverse block,” or expansion injury.

Differential Diagnosis and Medical Decision Making

Table 133.1 lists the differential diagnosis for dive injuries based on the time of onset of symptoms.

**Table 133.1** Differential Diagnosis of Dive Injuries Based on the Onset of Symptoms

<table>
<thead>
<tr>
<th>SYMPTOM ONSET</th>
<th>INJURIES TO CONSIDER</th>
</tr>
</thead>
</table>
| Descent       | Ear or sinus barotrauma  
                | Inner ear barotrauma    |
| Bottom        | Nitrogen narcosis      
                | Oxygen toxicity

|               | Trauma                 
                | Alternobaric vertigo    
                | Alternobaric facial palsy |
| 15 min after resurfacing | Arterial gas embolism |
| 15 min to 24 hr after resurfacing | Decompression sickness |

**Middle Ear Barotrauma ("Squeeze")**

Middle ear barotrauma (middle ear squeeze, barotitis media) is the most common disorder in divers and hyperbaric medicine patients. It usually occurs during descent as a result of an inability to equalize pressure across the TM. It occurs in 30% of novice divers and 10% of experienced divers. When water exerts pressure on the external TM and pushes it inward, a diver can usually equalize the pressure in the ears by swallowing, yawning, performing a Valsalva maneuver, or blowing against closed nostrils. Divers are often unable to clear their ears because of anatomic variability of the ET, inflammation, a viral infection, or upper aerodigestive dysfunction. Without equalization of the pressure, the TM ruptures. As little as 100 mm Hg (5 fsw) can create a pressure differential large enough to rupture the TM. Symptoms of middle ear barotrauma are ear pain, pressure, and muffled hearing. If the TM is ruptured, vertigo may occur because of the effects of cold water on the middle ear or TM. Treatment consists of decongestants, rest from diving, and follow-up with an otorhinolaryngologist (refractory cases). In general, these injuries are self-limited. However, if a patient needs hyperbaric medicine treatments, pressure equalization tubes may be placed to prevent middle ear barotrauma. Any form of TM rupture, placement of a pressure equalization tube, or...
myringotomy would be a contraindication to wet water diving because water comes in direct contact with the middle ear.

**Alternobaric Facial Palsy** Alternobaric facial palsy, a complication of middle ear barotrauma after diving, is a syndrome consisting of unilateral facial nerve palsy, ataxia, vertigo, nausea, and vomiting. The symptoms can be confused with those of AGE or DCS; however, the mechanism is elevated middle ear pressure pressing against the facial nerve and causing ischemic neurapraxia. Alternobaric palsy is also observed in those who fly after diving, fly at high altitude in unpressurized airplanes, and experience explosive decompression in flight. Though uncomfortable, the symptoms usually resolve within minutes once middle ear pressures equilibrate.

**Reverse Middle Ear Barotrauma** Reverse middle ear barotrauma, or reverse squeeze, is similar to middle ear squeeze but involves increased pressure in the middle ear pushing outward on the TM. It is often due to ET obstruction and occurs on ascent. The symptoms are similar to those of middle ear squeeze; however, reverse squeeze can rupture the round window as well.

**Inner Ear Barotrauma**

The inner ear is a complicated and delicate organ, and any diver complaining of hearing loss, vertigo, or ear pain might have inner ear barotrauma (IEBT). Though less common than middle ear squeeze, IEBT is associated with significantly higher morbidity because it often involves damage to the cochleovestibular organs. Separating the middle and inner ear are the thin membranes of the round and oval windows. Damage to these structures may cause leakage of fluid from the inner to the middle ear. IEBT can result from difficulty equalizing pressure during a dive. Performing a vigorous Valsalva maneuver or forcefully attempting to clear the ears can cause damage to the round window. The symptoms can be quite significant and include extreme dizziness, vertigo, nausea, and vomiting. The patient might also have nystagmus, ataxia, and hearing loss. IEBT is considered an emergency and mandates immediate evaluation by an otolaryngologist.

**Alternobaric Vertigo**

Alternobaric vertigo occurs on ascent as a result of differences in pressure between the two middle ear spaces. This difference causes asymmetric stimulation of each vestibular organ, which leads to vertigo. Symptoms include severe nausea and vomiting, as well as transient hearing loss. The patient will report abrupt relief with clearing of the ears or return to pressure.

**Sinus Barotrauma**

Sinus barotrauma (“sinus squeeze”) is the second most common disorder in divers, but it is significantly less common than middle ear barotrauma, with only 1% of divers affected. Symptoms include sinus pain on descent and bloody nasal discharge on ascent. Treatment consists of decongestants, antiinflammatory agents, and rest from diving.

**Pulmonary Barotrauma and Pulmonary Overpressurization Syndromes**

Pulmonary overpressurization syndromes can occur during rapid ascent with breath-holding in which the pulmonary parenchyma is ruptured. Ascending too fast without exhaling allows the rapidly expanding gases in the lungs to enlarge and stretch the lung parenchyma, followed by overdistention and ultimately parenchymal rupture. Gas then enters the perilingual spaces, which creates a pathway for bubbles to embolize to the brain. As little as an 80–mm Hg pressure differential is sufficient to rupture the alveolar lining. It can occur with breath-holding during the last 3 to 4 fsw of ascent.

**Pneumomediastinum and Mediastinal Emphysema**

Pneumomediastinum occurs when alveolar rupture allows gas to enter the mediastinum through the perivascular sheath; it causes chest pain and sometimes crepitus that is appreciated with auscultation (Hamman sign). Treatment consists of supplemental oxygen and observation; the diagnosis is made by chest radiographic evaluation and physical examination. Recompression is usually unnecessary, although a thorough neurologic examination to screen for AGE is recommended. Approximately 30% of divers with AGE will be found to have pneumomediastinum on a chest radiograph.

**Subcutaneous Emphysema**

Similar to pneumomediastinum, subcutaneous emphysema is due to alveolar rupture causing release of gas into tissues that can track up into the neck and under the skin. Symptoms include palpable crepitus, a sensation of fullness in the chest, possible alteration of voice, and occasionally dysphagia. Treatment is similar to that for pneumomediastinum; recompression is not generally necessary for isolated subcutaneous emphysema.

**Pneumothorax**

Pneumothorax is a severe, potentially life-threatening pulmonary overpressure syndrome. Rupture allows bubbles and gas to enter the pleural space, which can place pressure on the lung itself. Symptoms vary greatly, depending the volume of air entering the pleural space and the patient’s baseline lung function. Patients may have simple dyspnea or exhibit shock or life-threatening cardiac arrest (tension pneumothorax). The most common symptoms are sharp chest pain, shortness of breath, and occasionally a sudden, dry, hacking cough. Pain may also be felt in the shoulder, neck, or abdomen. Treatment is immediate administration of high-flow oxygen and possible needle decompression or tube thoracostomy (or both). If pneumothorax occurs during hyperbaric treatment or surface decompression table treatment, immediate venting of the pneumothorax (Heimlich valve) may be necessary to prevent the development of tension pneumothorax.

**Arterial Gas Embolism**

AGE, the most lethal result of pulmonary barotrauma, is a common cause of death in recreational divers. Its incidence is underestimated because many in-water deaths are classified as drowning. When rupture of the lung parenchyma leads to intravascular bubbles, these bubbles can embolize and cause end-organ damage. Sadly, this disorder is often seen in inexperienced divers who panic at depth and shoot to the surface without exhaling slowly. The symptoms are dramatic, usually LOC immediately or within minutes of the diver reaching the surface. Death is common. The arterial emboli are most deadly when they travel to the coronary or cerebral circulation. Cerebral AGE is manifested
very much like a stroke and results in headache, confusion, agitation, hemiplegia, or sudden LOC. Air embolism can also block blood flow through the coronary circulation and lead to cardiac ischemia, dysrhythmias, shock, and death.

Definitive treatment of AGE consists of high-flow oxygen on site and immediate hyperbaric recompression. The sooner patients are recompressed, the less likely they are to have permanent neurologic injury. Full recovery is common when recompression is available immediately. It is important to remember that AGE can occur in shallow water while breathing compressed gas or during breath-hold diving. This is in contrast to DCS, which usually occurs following a deep or prolonged dive when high nitrogen partial pressure develops.9 AGE also occurs in the hospital setting as a result of iatrogenic errors (central line manipulation, hemodialysis), but it can occur with any procedure or trauma that can entrain gas into the bloodstream.

Gastrointestinal Barotrauma
The stomach and intestine are both air-filled organs and, though rarely affected, are susceptible to barotrauma. Specifically, gas expansion occurring on ascent can cause nausea, belching, flatulence, mild stomach pain, and reflux. These symptoms resolve fairly quickly after the diver resurfaces because these spaces are typically easily vented.

Tooth Barotrauma
The small air pockets that exist in teeth and under fillings are susceptible to barotrauma (barodontalgia). Most people experience pain only on ascent, but tooth fractures have occurred (odontocrisis). Decompressions as mild as those experienced during commercial air flight pressurization (8000 feet or 0.75 ATA) are sufficient to cause barodontalgia. Such patients should be referred for dental evaluation, and divers should make their dentists aware of their diving hobby so that air pockets can be avoided.

DECOMPRESSION SICKNESS
DCS, or “the bends,” is a type of DCI that usually occurs after diving at deeper depths. In accordance with Dalton’s law, tissues become highly permeated with inspired inert gases with increasing depth. DCS can also occur after long shallow dives if significant tissue saturation has occurred. It can cause a spectrum of symptoms. Diagnosis can be difficult because divers may complain of only mild to moderate symptoms, which they tend to ignore or attribute to other causes. Frequently, a diver complains, “I just don’t feel right,” or has limb pain without trauma that is assumed to be muscular in origin. DCS symptoms rarely develop while the diver is in the water. The key to diagnosing dive-related injuries is to (1) elicit the timing of the onset of symptoms (before, during, or after a dive), (2) determine the presence of any dive-related DCS risk factors (dehydration, alcohol use, inexperience, failure to follow the decompression tables, flying after diving, reverse-profile diving, multiple dives per day, decompression diving, smoking, advanced age, cold water, patent foramen ovale, and obesity), and (3) have a low threshold for suspicion of DCS when symptoms develop. DCS is classically divided into three types according to the severity of illness and the location of symptoms. In reality, DCS symptoms overlap and the basic treatment is usually the same for all types—recompression with hyperbaric oxygen.

Type I (“Mild” Symptoms)
Type I DCS describes mild symptoms such as joint pain (most common), dermatologic manifestations, and lymphatic-associated swelling and edema as a result of the effects of gas bubbles in the tissues (Box 133.3). Bubble formation in joints is due to the greater negative pressure that exists in the joint spaces.10 Pain is most often felt in the shoulders or knees but can appear in any joint. The pain is gradual and aching and varies in intensity, usually worsening with time. Limb pain in divers affects the upper extremities three times more often than the lower extremities, and its distribution is often asymmetric.11 Caisson workers, however, are affected more often in their lower limbs.8 Merritt makes the point that type I DCS usually involves pain in the extremities whereas type II DCS usually involves central structures.7

Dermatologic DCI (“skin bends”) can have several manifestations. A diver can experience itching alone (without a rash) in localized or generalized areas of the arms, legs, face, or trunk (“fleas”). This form is commonly thought to follow dry dives, appears shortly after resurfacing, and lasts only a few minutes to a few hours.12 Other dermatologic manifestations of DCS are mottling (cutis marmorata) and rindlike skin (peau d’orange).

Type II (“Severe” Symptoms)
Type II DCS causes more severe symptoms that have a high risk of leading to major disability or death. Cardiopulmonary,

**Definitive Treatment**

Definitive treatment is recompression

All patients require oxygen. Remember to consult a hyperbaric medicine specialist early if the patient is being brought from a dive accident

neurologic, and inner ear manifestations predominate (Box 133.4). All patients with type II DCS symptoms require emergency recompression in a hyperbaric chamber. The sooner they are recompressed, the more likely they are to have a full recovery. However, even if treatment is delayed several days, recompression can still be helpful. Multiple treatments may be necessary to maximize recovery.

**Type III Decompression Sickness**
Type III includes both type II symptoms and AGE.

---

**TIPS AND TRICKS**

Limbs pain as a result of DCS usually persists even at rest, whereas the pain of a traumatic injury often improves with rest or nonuse.

Resolution of the pain at a joint when a blood pressure cuff is inflated is a strong indicator of joint DCS.

Neurologic examination of an injured diver is best performed with the patient out of the stretcher or bed to unmask any neurologic deficits.

Serious diving injuries are much more common in recreational divers than in commercial or military divers. Abdominal pain may be an early signal of spinal cord injury in divers with DCS.

*DCS, Decompression sickness.*

---

**NEUROLOGIC EXAMINATION**

The importance of performing a thorough neurologic examination cannot be understated. Unless an obvious neurologic deficit is noted, many dive-injured patients do not realize that they have an injury. However, if “hard” neurologic symptoms are observed, the patient requires immediate recompression with hyperbaric oxygen therapy without delay (Box 133.5).

The neurologic examination should include a diver’s mental status, cranial nerves, balance, coordination, sensory testing, deep tendon reflexes, pathologic reflexes, and both fine and gross motor skills. Preprinted neurologic examination forms enable the physician to maximize diagnosis and treatment, as well as to standardize findings.

---

**TREATMENT**

**PREHOSPITAL MANAGEMENT AND AIR EVACUATION FROM THE SITE**

Prehospital treatment of a dive injury is similar to that given in the ED. However, the hyperbaric team should be notified early that the patient is incoming to minimize delays (Box 133.6).

**EMERGENCY DEPARTMENT EVALUATION AND TREATMENT**

ED treatment of dive-injured patients must follow a standard approach. In addition to ordering routine laboratory tests, oxygen, and intravenous fluids, obtaining a thorough history is critical to treatment (Boxes 133.7 and 133.8).
BOX 133.6 Prehospital Treatment and Air Evacuation Instructions for Dive-Injured Patients

1. Maintain the ABCs of resuscitation and evaluate the patient’s serum glucose level.
2. Use ACLS protocols to stabilize the patient.
3. Administer high-flow oxygen, establish intravenous lines, and begin fluid administration.
4. Keep the patient flat; avoid the Trendelenburg position. If aspiration is a risk, lay the patient on the left side or in the right lateral position.
5. If air evacuation is being performed, ensure that the cabin of the airplane is pressurized or have the pilot fly at altitudes below 1000 feet.
6. Transport the patient along with all gear (it will have to be examined later).
7. Remember that the other members of the diving party might also need transport and evaluation for decompression sickness; they should accompany the patient to the ED.
8. Alert the consultant dive physician and hyperbaric center ahead of time that a dive injury has occurred and the patient is being brought to the ED.

ABCs, Airway, breathing, and circulation; ACLS, advanced cardiac life support; ED, emergency department.

BOX 133.7 Emergency Department Diagnostic Work-up for Dive-Injured Patients

**Laboratory Tests**
- Complete blood count
- Measurement of serum electrolytes
- Consider markers of injury LDH, CPK
- Oxygen saturation measurement

Add these tests for altered mental status:
- Urine and blood toxicologic tests with acetylsalicylic acid or acetaminophen and ethanol levels
- Arterial blood gas measurements, including a carboxyhemoglobin level

**Imaging**
- Consider the following evaluations for suspicion of pulmonary barotrauma:
  - Chest radiograph
  - Computed tomography of the chest (evaluation for blebs, small pneumothoraces, and other pulmonary problems)

who have experienced DCS or embolic dive injuries should be transferred immediately to the closest emergency hyperbaric facility. The physician should err on the side of caution; any patient with concerning symptoms should not be discharged until a hyperbaric physician has been consulted (Boxes 133.9 and 133.10).

**FLYING AFTER DIVING**

One of the most important factors in the disposition of divers is how long the diver should wait to fly after diving or a diving-related injury. Forgetting to counsel a patient about

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Although each patient is unique, many patients with DCI can be safely discharged from the hospital. However, any diver with serious DCS symptoms should be admitted. All patients

**PATIENT TEACHING TIPS**

Avoid diving when you have any symptoms of upper respiratory infection.
Do not drink alcohol and dive.
Never dive alone.
Do not dive and fly within the same 24 hours.
Do not “push” dive tables or dive profiles.
Do not perform heavy exercise after diving.
Drink plenty of fluids and get plenty of rest.
Plan deeper dives at the beginning of a dive trip.
A hyperbaric or dive medicine consultation should be sought immediately for divers exhibiting the following:

- ANY alteration in mental status
- ANY neurologic deficit
- ANY loss of consciousness
- ANY worsening of symptoms during evaluation
- ANY worrisome sign, symptom, or behavior
- ANY limb pain after ascent from depth

(919) 684-8111 or (919) 684-4DAN (collect)

DAN handles all diving emergencies, including decompression sickness, arterial gas embolism, pulmonary barotrauma, and other diving-related injuries. DAN’s medical staff is on call 24/7/365.

12. London Diving Chamber and Hyperbarics website. Available at www.londondivingchamber.co.uk/.
Submersion simply means going under water. To avoid confusion, especially in reporting, the International Liaison Committee on Resuscitation recommends that the following previously used terms no longer be used: dry and wet drowning, active and passive drowning, silent drowning, secondary drowning, and drowned versus near-drowned. In 2002, the World Congress on Drowning adopted a uniform definition of drowning: “the process resulting in primary respiratory impairment from submersion/immersion in a liquid medium.”

Drowning is an important cause of childhood morbidity and is among the top 10 causes of mortality (Fig. 134.1). Drowning is estimated to kill 500,000 people every year worldwide. Eighty percent of these episodes take place in low-income countries and low-income groups. About 80% of drowning episodes are deemed preventable.

Overall rates of drowning have dropped in all age groups, probably as a result of improved awareness, use of preventive measures, and other factors (Box 134.1). Inadequate supervision is the main risk factor for drowning in children. Most toddlers who drown do so in their own home pools, most infants drown in bathtubs, and adults and older children drown in fresh water. Fencing of private pools reduces the risk for drowning.

Injuries from drowning result mainly from asphyxia and subsequent hypoxic-ischemic damage to vital organs. The event starts with panic because of air hunger and, eventually, aspiration of fluid into the hypopharynx. Reflex laryngospasm occurs but is usually brief before the victim aspirates large amounts of fluid into the lungs. Further aspiration can occur if the victim vomits and aspirates gastric contents. Aspiration is the end result of all drowning, and the old terminology of dry and wet drowning should not be used. Changes in intravascular volume, hematocrit, and electrolyte concentration as a result of aspiration are usually mild and not clinically significant. Both salt water and fresh water cause lung injury. The effect of tonicity on the intravascular compartment is minimal.

The diving reflex is one of the unique phenomena described in children. Caused by vagal stimulation when the face is exposed to cold water (≤10°C), this reflex is characterized by apnea, bradycardia, and intense vasoconstriction. It is presumed that this reflex can play a neuroprotective role in cold water submersion. Hypothermia slows cerebral metabolism when the body has had time to cool before aspiration or with submersion in extremely cold water and may also contribute to neuroprotection.

Apnea, bradycardia, and intense vasoconstriction. It is presumed that this reflex can play a neuroprotective role in cold water submersion. Hypothermia slows cerebral metabolism when the body has had time to cool before aspiration or with submersion in extremely cold water and may also contribute to neuroprotection.

**CENTRAL NERVOUS SYSTEM**

Hypoxia and acidosis lead to neuronal injury, which results in diffuse brain edema and eventually increased intracranial pressure. Brain injury is the major cause of death and disability from drowning.
Inability to swim
Hyperventilation
Trauma
Use of alcohol and illicit drugs
Intoxications
Hypoglycemia
Seizures
Arrhythmias (long QT syndromes)
Child abuse and neglect
Vascular events (cerebrovascular accident, myocardial infarction)

CARDIOVASCULAR SYSTEM
Arrhythmias secondary to hypoxia and hypothermia are common. Sinus bradycardia, atrial fibrillation, and less commonly, asystole and ventricular fibrillation are reported to occur in patients who drown.

OTHER ORGANS
Acute tubular necrosis can develop but is uncommon. Significant electrolyte abnormalities are not seen unless drowning occurs in exceptionally concentrated media. Coagulopathy can occur with hypoxia but is uncommon.

PRESENTING SIGNS AND SYMPTOMS
Manifestations vary from no symptoms to death and depend on the severity of hypoxemia. Cervical spine injuries are uncommon with drowning unless trauma is suspected (e.g., diving and boating accidents, falls, crashes).

Respiratory signs and symptoms can vary in severity and may be delayed. They result from aspiration of fluid and loss of surfactant and include shortness of breath, wheezing (rhonchi, crepitations), pulmonary edema, and acute respiratory distress syndrome. Symptoms of aspiration pneumonia may develop later from aspiration of infected material.

Neurologic symptoms also vary. Patients may be asymptomatic, irritable, or confused; have seizures; or be comatose at initial evaluation. Deterioration can occur in asymptomatic patients and those with mild symptoms. Symptoms and signs of increased intracranial pressure appear late and are due to hypoxic brain injury.

Arrhythmias can also develop early or late and further compromise cardiorespiratory status. Hypoxia, acidosis, and hypothermia can lead to bradycardia, tachycardia, hypotension, hypertension, arrhythmias, and asystole.
DIFFERENTIAL DIAGNOSIS

Although the diagnosis of drowning is obvious, it is important to rule out medical conditions that may predispose a person to submersion, as well as the possibility of child abuse.

DIAGNOSTIC INVESTIGATIONS

Investigations are not as important on initial evaluation as clinical assessment and emergency therapy. Chest radiographic findings may be normal initially, even in symptomatic patients. However, pulmonary edema (localized or diffuse) and various degrees of atelectasis may be noted on examination. The initial chest radiograph will also help check endotracheal and gastric tube position. Measurement of arterial blood gas concentrations may be useful in guiding resuscitation efforts and in adjusting ventilator settings but should not be used as the sole predictor of outcome. Neuroimaging has no role in acute management but becomes important later to rule out unrecognized brain disease or to confirm hypoxic changes in the brain. When major trauma is suspected, the need for further imaging (e.g., head and cervical spine computed tomography [CT], abdominal CT) is determined by the severity of suspected injuries.

PROGNOSTIC FACTORS

AT THE SCENE

Performance of cardiopulmonary resuscitation (CPR) at the scene has been documented to improve survival in some cases, especially after cold water submersion. Generally, hypothermia is a poor prognostic sign unless the victim has fallen into extremely cold water (<10°C) or has undergone rapid cooling. Several case reports of survival of victims in such circumstances were attributed to a protective effect of cooling on the brain, which has led some authorities to recommend continuing CPR in hypothermic victims while actively rewarming them before declaring them dead.10

IN THE EMERGENCY DEPARTMENT

Many factors have been suggested as predictors of a bad outcome, but none alone were consistently reliable across studies. Prognostic factors such as a low Glasgow Coma Scale (GCS) score and ineffective respiratory efforts become more predictive after resuscitation and stabilization and hence may be more useful in the intensive care unit. Because no single prognostic factor is reliable in the immediate period after submersion, it is recommended that CPR be performed on most submersion victims until their condition is fully assessed.

TREATMENT

PREHOSPITAL MANAGEMENT

CPR at the scene is the most important initial step. It can be started even if the victim is still in the water. After the airway is secured and oxygenation and ventilation are ensured, the patient should be transferred to the nearest hospital. Further management at the scene depends on the availability of personnel experienced in advanced life support (Fig. 134.2). Most drowning victims should be transferred to an emergency department (ED) regardless of the initial appearance at the scene. Exceptions are those with obvious rigor mortis, lividity, and decay.

Emergency personnel dealing with a drowning victim should avoid the following:

- Maneuvers to expel water out of the lungs (i.e., abdominal thrusts)
- Cervical spine immobilization if no trauma is suspected
- Rough handling of a hypothermic patient (may induce arrhythmias)
- Delay in transport to the hospital after optimizing respirations

EMERGENCY DEPARTMENT MANAGEMENT

The main aims of treatment of a drowning victim in the ED are to avoid further hypoxia and restore effective ventilation and circulation (Table 134.1). ED personnel should assume the triad of hypoxia, acidosis, and hypothermia to be present in every drowning victim until proved otherwise. The need for cervical spine immobilization should be assessed, but in atraumatic drowning, immobilization is not mandatory. Vomiting occurs frequently, so early airway protection should be considered in distressed patients.

Airway

- For breathing patients, the FIO2 value should be kept at 1.0.
- For patients in respiratory distress, emergency personnel should have a low threshold for intubation. Treatment may start with positive pressure and positive end-expiratory pressure (PEEP) ventilation with a nasal cannula or mask.
**Exposure**
- The patient’s whole body should be exposed to check for injuries that might suggest trauma, abuse, suicide, and other causes.
- Rectal temperatures should be recorded.

</tbody>
</table>

- Indications for intubation are as follows: unconsciousness, respiratory insufficiency, and high O₂ requirements to keep the oxygen saturation value higher than 90% or Po₂ higher than 60 to 90 mm Hg (or both).

**Breathing**
- The oxygen saturation value and respiratory status should be checked. The onset of respiratory distress may be delayed and progressive.
- In cases of trauma, life-threatening disorders (e.g., hemothorax, pneumothorax) should be ruled out.

**Circulation**
- Vascular access, either intravenous or intraosseous, should be established.
- Arrhythmia, which can be the inciting event or a complication of hypoxia and hypothermia, should be ruled out.
- Fluid and electrolyte management and inotropic support are important to reverse depressed myocardial function, shock, and acidosis.

**Disability**
- The GCS score should be documented at baseline; it can be used to monitor the patient’s status over time because all drowning victims are at risk for worsening brain edema.
- Seizures can occur in patients with hypoxia, focal lesions, and worsening edema.

**MANAGEMENT OF HYPOTHERMIA**

For a detailed discussion of hypothermia, refer to Chapter 131. Hypothermia is defined as a core body temperature lower than 35°C. Depending on the temperature, hypothermia may be mild, moderate, or severe. This condition should be anticipated and treated in drowning victims. Notably, standard thermometers may not accurately measure low temperatures. Rewarming techniques are discussed in Chapter 131.

**NEXT STEPS IN CARE AND PATIENT EDUCATION**

Because of lung injury, loss of surfactant, and pulmonary edema, some patients will need higher end-expiratory pressure for optimal oxygenation. As PEEP is increased, blood pressure and cardiac output should be monitored because they can be compromised by high end-expiratory pressure. Intensive monitoring of cardiac, respiratory, and neurologic status and for complications such as aspiration pneumonia is indicated.

Some reports suggest that therapeutic hypothermia can improve neurologic outcome after out-of-hospital cardiac arrest and therefore recommend induction of hypothermia in drowning victims after restoration of spontaneous circulation.
Patients who are completely asymptomatic in the ED and whose arterial blood gas levels in room air, electrolytes, and chest radiographic findings are normal can be discharged after being observed for 6 hours. All others should be admitted to the hospital.

Acute Radiologic Emergencies

Bradley A. Dreifuss

KEY POINTS

- The nature and extent of an acute radiologic emergency should be identified to determine whether hospital disaster plans should be activated.
- Large-scale radiologic emergencies require triage of multiple patients based on the estimated radiation dose, presence of traumatic injuries, and availability of local resources.
- An emergency physician can use the symptoms and findings on physical examination to estimate the whole-body radiation dose (rad or gray) for predicting a patient's course and subsequent need for treatment.
- A complete blood count with differential at triage and 24 to 48 hours later can be used to guide the diagnosis, treatment, and prognosis of acute radiation syndrome.
- Decontamination is an important aspect of acute radiation emergencies but should not supersede stabilization of unstable patients.
- Recognition of patients who have been exposed to moderate to high doses of radiation and triage to early treatment of acute radiation syndrome can significantly decrease mortality.

EPIDEMIOLOGY

Acute radiologic emergencies are a rare occurrence, yet with increasing use of radioisotopes in medicine, research, and industry, as well as ongoing use in national defense and electrical power generation, it is imperative that emergency physicians (EPs) be versed in acute medical management after radiologic emergencies. The relative magnitude of the situation and the resources needed to address an emergency vary depending on the scale of the exposure event. Small-scale events include contained exposure in hospitals or research facilities or contained breaches at nuclear power plants in which small amounts of material may lead to exposure or contamination of a limited number of individuals. Large-scale events involve relatively large quantities of radioactive material or potential widespread exposure or contamination of a significant population. Examples of large-scale events include nuclear reactor meltdowns (e.g., Fukushima Daiichi, Japan, in March 2011; the Chernobyl meltdown in April 1986), detonation of nuclear weapons, or terrorist attacks with a radiologic dispersal device—otherwise known as a “dirty bomb.”¹ ² Hospitals are required by The Joint Commission to have disaster plans in place for mass casualty events, including radiologic emergencies, and EPs and emergency medical service personnel will be at the forefront of decision making and patient care when a radiologic event occurs.

The first priority during an acute radiation emergency is to establish the reality and type of radiologic event. Information received from the field is essential in mounting an effective response in the emergency department (ED) and the hospital. Important information to obtain from the field, if possible, is listed in the Documentation box. With large events, EDs should anticipate patients arriving from multiple field triage and stabilization sites, as well as individuals who arrive on their own accord without first being triaged or evaluated for injury or radiation exposure or contamination.

Communication between the field triage team and the ED must be clear because no federal or internationally agreed-upon medical triage systems have been established.

DOCUMENTATION

Important Information to Obtain from the Field After Acute Radiologic Emergencies

Type of radioactive material involved. Different types of radioactive material can expose patients in different ways. Important specifics include the type of radioisotope or source (α-, β-, γ-emitters, or neutrino), the form that it was in when the exposure occurred, and whether those exposed were also contaminated via inhaled dust or ingestion.

Types of traumatic injuries occurring with the radiation exposure (blast or burn).

Type of decontamination procedures taking place at the scene or in field triage.

Number of patients expected to require triage, evaluation, and treatment.

What local, regional, or federal resources have been activated and notified of the acute radiologic emergency.
The disaster response coordinator should prepare the ED to receive patients triaged at all levels with blast, thermal, and radiation injuries. Importantly, standard personal protective equipment sufficient to protect the emergency personnel treating these patients in the decontamination area and in the ED must be used.1,8-11 Those triaging and caring for patients with possible contamination should be using strict isolation precautions.

In any acute radiation emergency, initial mass casualty field triage should not be confused with the subsequent clinical triage used by EPs and other providers for more definitive medical management. It is essential that those involved in triage and provision of emergency care for radiologic emergencies understand that lifesaving medical stabilization takes precedence over other concerns, including external radiation decontamination.1,4,10-12

## Pathophysiology

Radioactivity refers to the loss of particles or energy from an unstable atom, that is decaying. There are two distinct types of radiation: ionizing radiation (e.g., α and β particles from a decaying radionuclide and nonparticulate electromagnetic γ-rays and x-rays) and nonionizing radiation (e.g., all forms of the electromagnetic spectrum, except for γ-rays and x-rays).

The main means of exposure to a dose of radiation are (1) from an external radiation source, (2) by loose radioactive material deposited on the skin or into wounds, and (3) by ingestion or inhalation of radioactive material.1 Significant radiation injuries can occur from irradiation with or without contamination (contact of the substance directly with human tissue). A contaminated patient will have been exposed to radioactive material that could still be on or inside the patient’s body. Irradiated patients without contamination have been exposed but do not have radioactive material on or in them. Irradiated patients are not “radioactive.” Such differentiation in a radiologic emergency situation is important because it dictates whether decontamination is needed. A radioactivity meter (most commonly a Geiger counter is the initial screening tool) and the patient’s history should be used to determine whether a patient has been contaminated.

To comprehend the physiologic effects of radiation, it is important to understand the units of measurement for types of doses (see the Facts and Formulas box). Radiation damage occurs within microseconds of exposure and most significantly affects rapidly reproducing types of cells (e.g., intestinal crypt cell, stem cells) or cells with a large nucleus, such as lymphocytes. The threshold of 2 Gy of whole-body irradiation is often used as the reference point for when cells have been irreparably damaged and symptoms of acute radiation syndrome (ARS) develop.1,12

### FACTS AND FORMULAS

#### Radiation Absorbed Dose

Amount of energy deposited in tissue by ionizing radiation measured in both U.S. and SI units:

- **U.S. unit = rad** (1 rad = 100 ergs [10⁻⁷ J] of energy deposited into 1 g of tissue)
- **SI unit = gray** (1 Gy = 1 J of energy deposited into 1 kg of tissue)
- Therefore, 1 Gy = 100 rad

#### Dose Equivalent or Equivalent Dose (SI Terms)

Difference in future risk (i.e., risk for induction of cancer) with different types of radiation and calculated by applying a constant that is unique for each type of radiation: quality factor (U.S.) and radiation weighting factor (SI)

- **U.S. unit = rem**
- **SI unit = sievert (Sv)**

For example, the constant for x-radiation or γ-radiation is

\[
100 \text{ rad} \times 1 = 100 \text{ rem}; 1 \text{ Gy} \times 1 = 1 \text{ Sv}
\]

#### Triage Formula for Irradiated Patients When CBC with Differential Is Available (Adapted from AFRRI, 2010; REAC/TS, 2011)

In otherwise healthy adult patients who have been exposed to external irradiation without trauma or burn, a clinically detrimental radiation dose can be distinguished from a dose lower than 1 Gy 4 hours after exposure by using a triage score involving two criteria: the N/L ratio and whether emesis has occurred in the 4 hours since exposure.

The triage score T is assigned as follows:

\[
T = \frac{N}{L} + E
\]

Given: \( N = \text{WBC} \times \% \text{ neutrophils}; \ L = \text{WBC} \times \% \text{ lymphocytes} \); \( E = 0 \) if no emesis is present by 4 hours; \( E = 2 \) if emesis is present by 4 hours

If T is higher than 3.7, the patient should be referred for further evaluation; otherwise can be discharged with follow-up if clinically stable

#### Background

In a normal, healthy human population, the N/L ratio from a CBC with differential has been found to be approximately 2.1. For time longer than 4 hours after the event, T is significantly elevated with doses higher than 1 Gy. Data from a REAC/TS Radiation Accident Registry was used in a case-control study (\( n = 226 \) controls, \( n = 36 \) radiation cases; median dose, 3 Gy) to show that this triage scoring tool has the ability to discriminate between patients with whole-body radiation doses lower than 1 Gy and those with higher, clinically significant doses (sensitivity of 89% and specificity of 93%).

*AFRRI*, Armed Forces Radiobiology Research Institute; CBC, complete blood count; N/L, neutrophil-lymphocyte ratio; REAC/TS, Radiation Emergency Assistance Center/Training Site; WBC, white blood cell.
**PRESENTING SIGNS AND SYMPTOMS**

Depending on the cause of the radiologic emergency (spill or leak versus explosion), the emergency provider may be in the position of having to stabilize and treat traumatic injuries and burns before assessing patients for signs of ARS. In cases of blast and thermal injury, patients’ traumatic injuries are of primary concern because poor outcomes after radiation injury are compounded by traumatic injury and thermal burns (e.g., combined injury).4,13

ARS is an acute illness that results from external exposure to radiation doses typically greater than 1 to 2 Gy (100 to 200 rad) delivered to a significant body surface area over a short period, and it occurs at an onset that varies from hours to weeks after exposure, depending on the dose. The severity and type of subsyndrome correspond to the amount and duration of exposure (dose).

ARS has four subsyndromes—hematopoietic, gastrointestinal, cutaneous, and neurovascular—and the time until onset and severity are related to the dose for all syndromes. The hematopoietic system is most vulnerable, with at least mild changes occurring at whole-body exposure to doses of less than 1 Gy, and acute treatment is typically considered at 2 Gy and higher.4,11,14 The cutaneous, gastrointestinal, and cardiovascular subsyndromes generally occur with whole-body exposure to doses of greater than 4 Gy, greater than 6 Gy, and greater than 10 Gy, respectively.11

ARS and the subsyndromes typically follow four predictable phases. The first, or prodromal, phase can include the symptoms of nausea and vomiting, diarrhea, fatigue, fever, erythema, conjunctivitis, and respiratory difficulty. Altered mental status occurs in the cardiovascular subsyndrome in association with very high radiation doses (>10 Gy). This prodromal phase indicates that more serious manifestations may follow and provides important clues for triage.5,9,12,14,15

Next is the latent phase, in which the symptoms subside; it lasts days to weeks, with patients exposed to higher doses typically having shorter latency. The latent phase is followed by the manifest illness phase, in which the four ARS subsyndromes are evident and patients require intensive medical management. The final phase is eventual recovery or death (Fig. 135.1; Table 135.1).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Given that modern supportive care is effective in increasing LD50/60 doses (lethal dose for 50% of the population surviving at 60 days) in nontrauma patients from 3.5 to 4 Gy (without medical care) to up to 6 to 8 Gy (treated with transfusions, antibiotics, colony-stimulating factors, and intensive care), it is of the utmost importance to triage and treat patients appropriately early in the postexposure period.5,9,10,11 The goal is to provide the highest level of care possible to patients.

---

**Fig. 135.1 Nature and time course of symptoms based on radiation dose.** Approximate times are listed for hematopoietic, gastrointestinal (GI), and central nervous system (CNS) symptoms at different ranges of whole-body radiation doses for exposed living persons. Symptoms include lymphopenia, granulocytopenia, and thrombocytopenia (hematopoietic); nausea, vomiting, and diarrhea (GI); and headache, impaired cognition, disorientation, ataxia, seizures, prostration, and hypotension (cerebrovascular). Relative severity is measured on an arbitrary scale. (Adapted from Waselenko JK, MacVittie TJ, Blakely WF, et al. Medical management of the acute radiation syndrome: recommendations of the Strategic National Stockpile Radiation Working Group. Ann Intern Med 2004;40:1037-51.)

who may have had radiation exposure, are possibly contaminated, and may or may not have sustained concomitant trauma or burns.

Although several well-known mass casualty triage systems such as START (Figs. 135.2 and 135.3) and JumpSTART have been devised, no federal or internationally agreed-upon on medical triage systems have currently been established specifically for radiation mass casualty incidents. Existing mass casualty emergency triage algorithms are currently being used with modifications for the impact of radiation and need for decontamination. However, large interorganizational efforts are currently being made at the federal level to further delineate triage protocols for different types of radiologic emergencies and for different levels of resource scarcity. See the Radiation Emergency Medical Management (REMM) website for up-to-date triage recommendations.

A significant aspect of triage is determining the degree to which the patient may have been irradiated and whether external or internal contamination is present. A Geiger counter and nasal swabs should be used at initial triage to

Fig. 135.2 START triage system used in mass casualty situations. START, Simple triage and rapid treatment.
determine whether a patient is externally (or potentially internally) contaminated. This should help dictate the amount and type of decontamination required to minimize the radiation dose. Removal of clothing alone is typically responsible for 70% to 90% of the external decontamination. In the setting of trauma and burn injury, additional wound decontamination and early wound care are necessary (see the Tips and Tricks box).

Radiation injury and traumatic injury (blast and burn) interact synergistically. Patients with traumatic or burn injury who have been subjected to significant whole-body irradiation (>2 Gy) have a substantially worse prognosis because of effects on the hematopoietic syndrome and high risk for infection and poor healing. Consequently, they require a higher triage priority than those who are only irradiated (with or without contamination) and should be triaged and treated according to the Armed Forces Radiobiology Research Institute (AFRRI) treatment protocol (Fig. 135.4).

Although the REMM website has very useful biodosimetry tools to assist in estimation of the radiation dose, it requires that blood samples be collected for a complete blood count (CBC) with differential and other laboratory tests (Box 135.1). However, because early in a large-scale acute radiologic emergency it may not be possible to process large numbers of blood samples, it may be necessary to use the history and symptoms (mainly time from exposure to the onset of persistent vomiting) (Table 135.2) with other findings on physical examination (Table 135.3) to estimate the whole-body radiation dose for triaging patients to the four levels of care—expectant, immediate, delayed, and minimal. Ideally, all patients triaged higher than “minimal” should undergo additional work-up, including blood work and urine testing for more sensitive and specific biodosimetric radiation dose estimation. Current recommendations include obtaining a CBC with differential at baseline and every 6 hours for at least the first 48 hours because lymphocyte depletion follows dose-dependent first-order kinetics and the neutrophil-lymphocyte (N/L) ratio increases over the first 48 hours after exposure—a sensitive indicator of the radiation dose (Table 135.4).

The U.S. Department of Defense has used the Radiation Emergency Assistance Center/Training Site (REAC/TS) database of patients with radiation exposure and symptoms combined with the N/L ratio to create a triage score that differentiates patients exposed to a high radiation dose from those exposed to less than 1 Gy. It can be used in patients seen 4 or more hours after an exposure and has a sensitivity of 89% and specificity of 93% (see the Facts and Formulas box).

**TIPS AND TRICKS**

**Recommendations for Radiologic Decontamination**

**Principles of Radiologic Decontamination**

Ideally, decontamination takes place at field triage (area away from the emergency department [ED]), and patients arrive at the ED for evaluation and treatment already largely decontaminated. The exception should be when patients require medical stabilization and resources are available for the expected volume of severely injured patients.

The hazard of radiation exposure by health care providers from a radiologically contaminated patient is probably negligible when recommended personal protective equipment is used.

Decontamination begins after the patient is medically stabilized.

Patients with a risk for external or internal contamination should be evaluated with a Geiger counter and the nares swabbed and tested to evaluate the risk for inhalation of radioactive material.

Decontamination priorities are (1) wounds, (2) body orifices around the face, and (3) intact skin.

Patients should be reassessed with a Geiger counter after every attempt at decontamination (e.g., removal of clothing, washing, and wound cleansing). Decontamination procedures should be continued until less than two times the normal amount of background radiation is present.

All wound care material, irrigation fluid, and water used for washing or showering should be contained and disposed of properly as radioactive waste.

**Decontamination Techniques**

Clothing is removed by rolling the clothes off in an outward direction and away from the patient’s skin and airway so that any radioactive contamination is trapped in the rolled clothing, and the clothing is placed in a sealed bag. Clothing should be cut, not torn.

Wound dressings are to be removed and the skin adjacent to the wound cleaned before cleaning the wound to prevent contamination of the wound. Areas around wounds should be draped to prevent contamination of the skin during copious wound irrigation.

Partial-thickness burns should be cleaned well with nonirritating solutions. Blister should be left closed; open blisters should be irrigated well and treated as all other open partial-thickness burns.

Full-thickness burns with radioactive contaminants warrant typical care because of contamination sloughing with the eschar.

Data from references 1, 8 and 22.

**TREATMENT**

The mainstay of acute medical treatment in a radiologic emergency is similar to the typical acute medical and trauma management in the ED, with attention paid to threats to life and limb first and symptomatic treatment as needed.

In ARS diagnosed by the onset of symptoms or biodosimetry assessment, treatment is based on the whole-body radiation dose. In general, treatment of ARS is not indicated for (1) a low exposure dose (<1 Gy) because the risk for complications is low and (2) a very high exposure dose (>10 Gy) because the prognosis is very poor in this population and palliative care is most appropriate. With exposure to greater than 2 to 3 Gy, medical treatments are both supportive (appropriate use of intravenous fluids, antiemetics, and nutritional support) and preventive (prophylactic antibiotics, colony-stimulating factors, and transfusion of blood products) (Box 135.2).
### BOX 135.1 Recommended Testing in Acute Radiation Emergencies

Recommended initial laboratory tests (all patients with suspected irradiation):
- Complete blood count with differential and absolute lymphocyte count at baseline and at 48 hours
- Serum amylase at baseline and at 24 hours (if feasible); radiation dose–dependent increase expected after 24 hours
- Urine pregnancy test—advisable for women of child-bearing age

If the patient is vomiting less than 3 hours after exposure:
- CBC with differential and absolute lymphocyte count repeated every 6 to 12 hours
- Type and crossmatch for possible need for transfusion of blood products
- HLA subtyping for possible future need for stem cell transplantation
- Cytogenetic dosimetry—dicentric chromosome assay (if feasible)

If the history indicates internal contamination (inhalation or gastrointestinal):
- Twenty-four-hour urine sample (name of radioactive isotope)
- Stool sample (name of radioactive isotope)

Data from references 1, 2, 9, 12, and 17.

- Antivirals
- Antifungals

**Preventive and Restorative**
- Colony-stimulating factor
- Transfusions

**Special Considerations**
- Potassium iodide for pregnant women

Data from references 10, 11, and 21.

Hospital treatment of ARS is focused on supportive measures and management of the hematopoietic subsyndrome to minimize the complications of sepsis and bleeding. The goal is to reduce both the depth and duration of neutropenia and thrombocytopenia, as well as to prevent or manage neutropenic fever and sepsis. Treatment recommendations for antibiotics (fluoroquinolone, acyclovir, and fluconazole) and cytokine therapy (hematopoietic colony-stimulating factors) vary depending on the estimated dose of radiation exposure, the presence of traumatic injury or burn, and the size of the...

For those with trauma and burns, there are caveats for decontamination of wounds (see the Tips and Tricks box). Because of the increased likelihood of infection and bleeding as a result of the hematopoietic effects of radiation exposure, any orthopedic reductions, splinting, casting, or surgery (orthopedic and otherwise) should be completed within the initial 48 hours of significant radiation exposure (>2 Gy).1,2,9

In addition to the aforementioned general recommendations for treatment of radiologic emergencies, specific approaches for treating internal contamination (ingestion or inhalation) have been established. Reduction of the internal radionuclide content is called radionuclide decorporation and can be helpful in reducing the absorbed radiation dose.18 Approaches to decorporation include (1) reducing or inhibiting absorption in the gastrointestinal tract, (2) blocking uptake to the organ predisposed to injury (e.g., potassium iodide for blocking uptake by the thyroid), (3) diluting the isotope and radiologic emergency, which is addressed in Table 135.5.
increasing elimination, (4) altering the chemistry of the substance, (5) displacing the isotope from receptors, (6) using chelation techniques to enhance elimination, (7) excising radionuclide from contaminated traumatic wounds early to minimize absorption, and (8) performing bronchoalveolar lavage for severe cases of insoluble inhaled particles.1,2

Treatment options are available if the radioactive contaminant is known and antidotes exist.2,9,10,19,20 Poison control centers can provide help in identifying potential antidotes for the ingestion of known radionuclides. A limited selection of radionuclide-specific decorporation treatments are included in Table 135.6. In general, the risk versus benefit balance of using these decoration agents depends on the estimated dose ingested and the time since the ingestion. Estimation of ingested radionuclide doses is typically beyond the scope of EPs and ED staff, and in many situations these treatments are not helpful early in the medical response following a large-scale radiologic disaster.1 Therefore, guidance from poison control, the Centers for Disease Control and Prevention, or REMM (or any combination of these resources) is recommended before beginning treatment.3,18,21

Importantly, after a nuclear detonation or nuclear reactor incident, radioactive iodine is a significant concern, and specific treatment might include potassium iodide (KI).2,8,19,22 The decision to treat with KI will probably involve multiple agencies, including the U.S. Centers for Disease Control and Prevention, the U.S. Food and Drug Administration, and the U.S. Department of Health and Human Services, and guidance should be sought before treating.9,21 If indicated after a nuclear disaster, KI should be administered before or immediately coincident with passage of the radioactive cloud, although KI may still have a substantial protective effect even if taken 3 or 4 hours after exposure. Consult the REMM website or desktop application for prescribing details and note that pregnant women and children deserve special consideration for KI given their increased risk for malignancy and thyroid disease over time.10,20

The psychologic impact of a nuclear event can be overwhelming2,21,24 and should not be underestimated. It has been suggested that if possible, educational material and counselors should be available at triage and receiving centers, as well as in the ED, and patients should be given instructions to see a health care provider if they are having signs of psychologic stress.1,8,25

NA, Not applicable; SCT, stem cell transplantation.

*Consensus guidance for treatment is based on threshold whole-body or significant partial-body exposure. Events caused by detonation of a radiologic dispersal device resulting in 100 or fewer casualties and those caused by detonation of an improvised nuclear device resulting in more than 100 casualties have been considered. These guidelines are intended to supplement (and not substitute for) clinical findings based on examination of the patient.

†Prophylactic antibiotics include a fluoroquinolone, acyclovir (if the patient is seropositive for herpes simplex virus or has a medical history of this virus), and fluconazole when the absolute neutrophil count is lower than 0.500 × 10^9 cells/L and the patient is not already receiving colony-stimulating factor.

‡Consider initiating therapy at a lower exposure dose in nonadolescent children and elderly persons. Initiate treatment with granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor in victims with an absolute neutrophil count lower than 0.5000 × 10^9 cells/L who are not already receiving colony-stimulating factor.

§Absolute neutrophil count lower than 0.5000 × 10^9 cells/L. Antibiotic therapy should be continued until neutrophil recovery has taken place. Follow the Infectious Diseases Society of America guidelines for febrile neutropenia if fever develops while the patient is taking prophylactic medication.

¶If resources are available.

#### FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Disposition after a radiologic emergency depends on several factors, including the estimated radiation dose and associated trauma or burn. Patients who remain asymptomatic or only minimally symptomatic without persistent vomiting were probably triaged as “minimal” (radiation exposure < 1 Gy)
Table 135.6 Specific Decorporation Treatments in Patients with Internal Radiation Contamination*

*Seek guidance from the Centers for Disease Control and Prevention or Radiation Emergency Medical Management (REMM) when administering any of these interventions because many have an unfavorable risk-to-benefit ratio in those with ingestion of a low to moderate dose. Treatment is strongly recommended for ingestion doses 10 times the annual limit of intake (REMM, 2011).

†Only potassium iodide, diethylentriaminepentaacetic acid (DTPA), and Prussian blue are approved by the Food and Drug Administration for decorporation (REMM, 2011).

Moderately symptomatic patients or those who have absorbed more than 2 Gy and are experiencing symptoms are hospitalized for observation and treatment of ARS and any injuries. Patients with moderate injury or burn (>10% body surface area) and moderate to severe ARS should taken to surgery (if needed) within 36 to 48 hours, as well as be treated for ARS in an inpatient setting.2,10,12 Within these recommendations for disposition, it is specifically noted that any transfers to larger facilities for surgery or management of severe ARS should take place in the first 48 hours when possible to enable the greatest likelihood of a good outcome.

Severely symptomatic patients with gastrointestinal and cardiovascular syndromes (>10 Gy) of absorbed radiation are treated with as many resources as reasonable for the situation in recognition of the fact that the prognosis is very poor regardless of interventions. In the setting of a mass casualty, these patients are managed expectantly (i.e., with comfort measures for pain, nausea or vomiting, and anxiety). Similarly, patients with moderate to severe trauma or burns and more than 6 to 8 Gy of absorbed radiation dose will often be managed expectantly. In isolated cases, empiric antibiotic therapy, colony-stimulating factor therapy, transfusions, and a search for bone marrow donors might ensue in a heroic attempt to save the patient’s life.2,10,12 Unfortunately, data and experience in identifying the optimal disposition of children and the elderly who have experienced irradiation and trauma are limited, so clinicians will have to decide each case individually.12

Smoke Inhalation

Thomas Kunisaki and Steven A. Godwin

mixture of suspended small particles, fumes, and gases. More than 400 toxic compounds have been demonstrated in the smoke of a typical house fire. Polyvinyl chloride, a component of many plastic goods, generates at least 75 different toxic products when burned. Of these toxic substances, carbon monoxide (CO) appears to be the most common fatal substance associated with fire victims.5,6

Thermal inhalation injuries are usually localized to the upper airway. Irritant gases, depending on their water solubility, affect either the upper or lower airway. Highly water-soluble agents such as ammonia, hydrogen chloride, and sulfur dioxide predominantly affect the upper airway. Their solubility directly correlates with rapid adverse upper airway symptoms. Agents with lower water solubility, such as phosgene and nitrogen dioxide, which do not produce immediate irritation, will be inhaled deeper in the pulmonary system and result in injury to the alveoli; victims typically have delayed noncardiogenic pulmonary edema.

Asphyxiants further compound the injury in smoke inhalation victims. Simple asphyxiants, such as carbon dioxide and methane, will produce an oxygen-deprived environment. Systemic asphyxiants, such as CO, cyanide, and hydrogen sulfide (H2S), will prevent utilization of oxygen by cells. Either mechanism will promote an anaerobic state and the development of lactic acidosis.

CO is a colorless, odorless, nonirritating gas produced by the incomplete combustion of hydrocarbons and petroleum distillates, whether from a fire, fuel source, or automobile exhaust or from the metabolism of methylene chloride, a solvent commonly used as a paint stripper. One of the major mechanisms of CO toxicity is its affinity to bind hemoglobin, with an affinity estimated to be approximately 250 times greater than that of oxygen, which results in reduction in oxyhemoglobin. The impairment in delivery of oxygen is exacerbated by displacement of the oxygen dissociation curve to the left. Furthermore, CO interferes with cellular respiration by binding to mitochondrial cytochrome oxidase and is involved in the formation of oxygen free radicals and subsequent lipid peroxidation. All the aforementioned mechanisms produce oxidative stress on the brain, the main organ affected by CO; excitatory amino acids such as glutamate are activated, which results in neuronal injury and cell death. Areas of the brain that are highly sensitive to hypoxemia, such as the basal ganglia, appear to sustain the most injury. CO is known to bind to myoglobin as well, a feature that contributes to impairment in myocardial contractility. Fetal hemoglobin is more

KEY POINTS

- The majority (60% to 80%) of deaths attributable to fire are caused by smoke inhalation rather than burns.
- Smoke is a combination of heated particles and gases (toxicants).
- Carbon monoxide has been implicated in more smoke inhalation deaths than any other single compound.
- In addition to inhalation of toxicants, smoke inhalation can cause upper airway burns that result in pulmonary parenchymal injury.
- The mainstay of treatment consists of ventilator support, early intubation, optimization of fluid resuscitation, pulmonary hygiene, and treatment of specific toxicants.

EPIDEMIOLOGY

Fires are common events in the United States. It is estimated that fire departments respond to fire alarms every 20 seconds.1 In 2007, more than 1 million fire incidents and nearly 3500 deaths were reported, with civilian fatalities occurring every 153 minutes on average.1 An estimated 50% to 80% of fire-related deaths are the result of smoke inhalation. Incident after incident, most of the victims of fires in commercial buildings, such as clubs, escape burns but suffer from smoke inhalation.

Smoke inhalation injuries related to fire result from the toxic gases generated. Deaths from smoke inhalation have increased in recent years because of the abundant use of newer synthetic material in building and furnishings.2

PATHOPHYSIOLOGY

Deaths from fires are most often caused by smoke inhalation.3-4 The injury from smoke inhalation is a result of direct thermal injury to the airway and lung parenchyma, as well as mucosal irritation, corrosive injuries, and asphyxiation from toxic gases. Toxic gases can be classified as irritant gases and asphyxiants. The danger from such toxic gases predominates in exposed fire victims. Smoke is composed of a complex

136
sensitive to the binding of CO; levels are reported to be approximately 10% higher than maternal levels, with a half-life five times longer. Over time, carboxyhemoglobin will dissociate, with its half-life on room air being approximately 4 to 6 hours. With 100% oxygen, the half-life decreases to approximately 90 minutes, and in the setting of hyperbaric oxygen therapy, it is about 20 minutes.

Cyanide is a highly toxic chemical. Hydrogen cyanide is a common by-product of the pyrolysis of wool, silk, and plastics. Cyanogenic compounds such as nitriles are used in industry as solvents and adhesives and are metabolized by the body to cyanide. Acetonitrile, which in the past was commercially available as an artificial nail glue remover, has resulted in fatality when accidentally ingested. With increasing concern about terrorism, it is high on the potential lists of chemical agents. Its mechanism is binding of the cytochrome aa₃ site on the electron transport system of mitochondria. The result is an inability to use oxygen and subsequent cellular asphyxia.

H₂S is the by-product of certain industries, such as paper factories, petroleum refineries, and dehairing of hides. It is produced naturally from decay of organic matter and from sulfur hot springs. These products have the characteristic “rotten egg” odor. Like cyanide, it is a potent inhibitor of the cytochrome oxidase system. The human nose is exquisitely sensitive to the odor of H₂S, and it is easily detected at levels as low as 0.13 parts per million (ppm). Irritation of mucous membranes occurs at levels of approximately 50 to 100 ppm, and such levels are also capable of causing bronchospasm, blepharospasm, and laryngeal edema. At levels greater than 500 ppm, a phenomenon classically described as a “rapid knockdown” effect occurs, which includes immediate loss of consciousness with the potential for cardiovascular collapse and respiratory arrest. Sulfhemoglobin may result from exposure to H₂S. Clinically, it may produce cyanosis. Unfortunately, it is an extremely stable compound and is eliminated only when the red blood cells are removed from the circulation. Recently, H₂S was a popular means of suicide in Japan.

Bath sulfur, a product readily available, is added to water to mimic the water of natural sulfur hot springs. However, when the bath sulfur is combined with acid, such as toilet bowl cleaner, a lethal H₂S gas is liberated. Any sulfur-containing substance, including laundry detergent, is a suitable substitute for bath sulfur. Reports of suicide in the United States with this method have been described in the media.

Methemoglobin is the oxidized form of hemoglobin and can result from exposure to oxidizing agents, such as nitrates and nitrates, as well as from smoke inhalation. In this oxidized state, hemoglobin is no longer capable of carrying oxygen. Cyanosis is typically seen at levels approximately of 15% to 20%. Levels greater than 70% are usually lethal.

Differential Diagnosis and Medical Decision Making

As a means of better understanding this complex problem, dividing smoke inhalation injury into toxidromes (toxic syndromes) may help identify clinically significant smoke inhalation. Aside from the potential concomitant thermal injuries associated with structural fires, these major toxidromes involve irritant gases, simple asphyxiants, systemic asphyxiants, and methemoglobinemia (Table 136.1).

Irritant gases can be divided into highly water-soluble and poorly water-soluble agents. Moderately water-soluble gases, such as chlorine, behave more like the highly water-soluble agents and are thus combined with the highly water-soluble agents. Highly water-soluble agents are very irritating to the mucous membranes, eyes, and upper airway, and affected individuals experience symptoms immediately. As with thermal injuries, early orotracheal intubation should be a priority in any individual with any degree of respiratory distress. These individuals can deteriorate rapidly. Generally, most individuals will be able to remove themselves from such an environment; however, if they are injured, incapacitated, or involuntarily confined, their outcome may be lethal. A prime example is the 1984 incident in Bhopal, India, where approximately 20,000 lb of isocyanate leaked from a nearby storage tank. By the time that the leak was discovered, the fumes covered nearly 5 square miles. It is estimated more than 200,000 individuals were victimized by the irritant gas and thousands of people died.

Poorly water-soluble gases have very poor warning properties, and thus they are inhaled deeper in the pulmonary system and affect the alveoli. Two examples of such agents are phosgene and nitrogen dioxide. The hallmark of these inhalation injuries is delayed pulmonary edema.

The asphyxiants toxidromes can be divided in simple and systemic. As asphyxiants, these agents affect the availability or utilization of oxygen by cells and therefore tissues and organs. Simple asphyxiants are generally inert gases, such as carbon dioxide, but they may be flammable, such as methane, and create an explosive hazard. Simple asphyxiants displace oxygen and thus create a hypoxic environment. Symptoms depend on the severity of the hypoxia and the duration of exposure. Because of the underlying mechanism, an excess...
of deoxyhemoglobin, cyanosis is usually present. Systemic asphyxiants impair the body’s ability to use oxygen by interfering with the transportation of oxygen, such as with methemoglobinemia, or by interfering with the utilization of oxygen at the cellular level, such as with cyanide. CO impairs both the transportation and utilization of oxygen.

The diagnosis of cyanide toxicity is generally based on a high index suspicion from the history. The victim will appear in a shocklike state. The classic bitter almond odor of cyanide is rarely detected. Hypoxia is a late finding because of its underlying pathophysiology. Oxygen is available, but the cells and tissues are unable to use it. Because cyanide assay is not immediately available in most institutions, indirect evaluation of the difference in the oxygen content of arterial and venous blood can provide valuable insight. A small arterial (PaO2)-venous (PvO2) oxygen gap would support the diagnosis. Severe lactic acidosis should prompt further investigation of cyanide toxicity. A lactic acid level greater than 10 mmol/L has been correlated with a cyanide level of approximately 40 mmol/L, a level considered significant and warranting immediate action.

Methemoglobinemia is the result of oxidation of the iron in hemoglobin. Normal hemoglobin has iron in the 2+ state. When it is exposed to an oxidizing agent, the iron is converted to the 3+ state. In this oxidized state, it is unable to bind oxygen. A methemoglobin level of approximately 1.5 g/dL can produce cyanosis. The body normally reduces iron by various physiologic pathways, primarily via reduced nicotinamide adenine dinucleotide (NADH) methemoglobin reductase and by a minor pathway, reduced nicotinamide adenine dinucleotide phosphate (NADPH) methemoglobin reductase. This latter pathway is dependent on a functional glucose-6-phosphate dehydrogenase (G6PD) system. It is the pathway that is the target of administration of methylene blue, the treatment of methemoglobinemia.

### TREATMENT

The priority of treatment is supporting and stabilizing the primary survey—the ABCs (airway, breathing, and circulation). Aggressive airway management is essential, including high-flow supplemental oxygen and early orotracheal intubation and ventilator management if necessary.

Close monitoring is imperative to observe for the potential for rapid clinical deterioration. Good supportive care is vital and includes fluid resuscitation, anticonvulsant therapy, and correction of metabolic abnormalities, especially metabolic acidosis.

Hydroxocobalamin (Cyanokit) is a new cyanide antidote approved by the Food and Drug Administration in December 2006. It has essentially replaced the older antidote, which used...
sodium nitrite to generate a controlled methemoglobinemia, follow by the administration of sodium thiosulfate, a substrate required by the liver enzyme rhodanase to then detoxify the formation of cyanomethemoglobin. Use of hydroxocobalamin is indicated in any individual with cyanide toxicity or suspected cyanide toxicity. By mechanism, it binds to cyanide to form cyano-cobalamin, which is vitamin B_{12}. It appears to be safe, with just a few clinically significant adverse effects, such as allergic reactions and transient hypertension. Generalized erythema and red chromaturia because of the dark red nature of the antidote once reconstituted are commonly reported. Unfortunately, laboratory studies that depend on colorimetric analysis are affected and will give false readings. Its clinical significance is unknown. Because of its safety profile, this antidote can be administered empirically at the scene of a fire to victims and fire rescuers who may be deemed at risk for toxic exposure to cyanide.\textsuperscript{10} In at least one animal study evaluating the effect of hydroxocobalamin on mice poisoned with sodium sulfide (at a lethal dose for 90\% of the population [LD\textsubscript{90}]), the antidote resulted in improved survival following its administration.\textsuperscript{11}

Methylene blue is the antidote for the treatment of methemoglobinemia. It is indicated in victims who are symptomatic and usually with methemoglobin levels greater than 20\% to 30\%. One contraindication to its use is G6PD deficiency. With multiple dosing, methylene blue may itself generate methemoglobinemia or cause hemolysis. Other therapeutic options for the treatment of methemoglobinemia are exchange transfusion or hyperbaric oxygen (HBO) therapy.

Treatment of CO toxicity is primarily supportive with 100\% supplemental oxygen. HBO therapy has been studied clinically for years, but its role in treating CO toxicity remains controversial.\textsuperscript{12,13} If considering HBO, generally accepted indications would include the following: loss of consciousness at the scene, comatose state, seizure, myocardial ischemia, and levels greater than 30\% in adults and greater 15\% in infants, children, or pregnant women.

### Follow-up, Next Steps in Care, and Patient Education

All smoke inhalation patients should be evaluated in an emergency department. If symptomatic, all will require admission. Depending on the severity of their exposure and injuries, they should be admitted to a monitor setting, including the intensive care unit if needed.

Patients with a brief exposure who are asymptomatic for a minimum of 6 hours can be discharged with good instructions to the patient and family member regarding the signs and symptoms of early respiratory distress, as long as they have the ability to access 911.

Patients in whom phosgene or nitrogen dioxide gases may be involved in the exposure should be admitted, despite being asymptomatic, and be observed for minimum of 24 hours with frequent assessment for signs and symptoms of delayed pulmonary edema.

137 Chemical and Nuclear Agents

Christopher S. Kang and Ian S. Wedmore

KEY POINTS

- Decontamination should take place immediately, before initial treatment and evacuation of exposed patients.
- For patients exposed to nerve agents, atropine and pralidoxime chloride should be administered rapidly.
- Treatment of blast injuries and emergency medical conditions should precede specific treatment of radiation exposure.

PERSPECTIVE

Casualties involving chemical and radiologic or nuclear agents have traditionally been associated with military armed conflicts. However, over the past 25 years, with the increased production and distribution of industrial chemicals, as well as the escalating threat of terrorist use of weapons of mass destruction, management of casualties from chemical, biologic, radiologic, nuclear, and high-yield explosive events has increasingly become the responsibility of the EP.

Initially approved in 1999 and revised in 2006, the American College of Emergency Physicians (ACEP) issued a clinical policy statement that recognized the risk posed by accidental or intentional release of chemical and nuclear hazardous material (HAZMAT). In another clinical policy statement, the ACEP also encouraged EPs to assume a primary role in the medical aspects of planning, management, and patient care during disasters, including those involving chemical, radiologic, and nuclear agents.

EPIDEMIOLOGY

Tens of thousands of chemicals are manufactured, transported, and used every day. The 1984 Bhopal, India, disaster revealed the dangers posed by chemical agents. A 2008 U.S. Department of Health and Human Services database of 14 states reported more than 15,000 chemical-related events and over 4500 casualties. Since World War I, chemical agents have also been used intentionally on civilian and military personnel, most recently in Japan in 1994-1995, in Russia in 2002, and in Iraq in 2007. Of the 13 categories of chemical agents recognized by the U.S. Centers for Disease Control and Prevention, the four principal categories are nerve, vesicant, blood, and pulmonary agents (Box 137.1).

Detonation of an atomic bomb over Hiroshima, Japan, in 1945 heralded the evolution of a new hazardous agent, radioactive material. Showcased by the 1987 accidental exposure of cesium 137 in Goiânia, Brazil, the threat from radiologic material has continued to increase with the proliferation of medical devices and radiation therapy. Though reduced by the end of the Cold War, the threat from nuclear agents continues to persist in light of the accidents at Chernobyl, Ukraine, in 1986 and Tokaimura, Japan, in 1997, as well as the acknowledgment that dozens of nuclear devices are missing.

Management of casualties from chemical and radioactive agents can be complicated by the types of agents and exposure, in addition to specialized logistic, safety, and security issues. Emergency physicians (EPs) must be familiar with the basic principles of managing contaminated patients and initial treatment of the principal chemical and radioactive agents.

BASIC PRINCIPLES OF MANAGING CONTAMINATED PATIENTS

Management of casualties from chemical and radioactive agents can be complicated by one or more factors, such as the number of patients, type of agent or agents involved, severity of the exposure, and the availability of pharmaceutical and human resources. A current and accurate hazard vulnerability analysis is essential for an optimal response to a specific identified hazard. However, because no facility can prepare for every possible factor and scenario, adherence to several basic principles may facilitate effective management of contaminated patients.

COMMUNICATION AND MOBILIZATION

Most events involving chemical or radioactive agents are rapidly identified by emergency services. Notification of health care facilities of a HAZMAT incident and casualties must also take place rapidly because 50% to 80% of the acute casualties will arrive at the closest health care facilities within 90 minutes following an event. Some casualties may leave the scene under their own power and go to a nearby health care facility, even before other patients arrive via emergency medical services.
Chemical Agents

CHAPTER 137 ▪ CHEMICAL AND NUCLEAR AGENTS

</tbody>
</table>

Concise and accurate communication of prehospital events is also crucial for an effective response. Collection of pertinent strategic details can guide mobilization of appropriate resources, including activation of an emergency management plan and the incident command system, consultation with material safety data sheets and HAZMAT experts, compilation of antidotes and medical equipment, and preparation of triage, decontamination, and personnel protection equipment.

DECONTAMINATION

Decontamination should take place immediately, before initial treatment and evacuation of exposed patients. Although decontamination is usually completed at the scene before transportation, exposed and potentially contaminated patients may go on their own to nearby health care facilities. In addition to requiring primary decontamination and triage, these patients may secondarily contaminate existing patients and medical personnel and thus create additional casualties and diminish the response by the affected facility.

Removal of contaminated clothing can eliminate 70% to 90% of HAZMAT. Once completed, patients should be showered if incapacitated—with copious amounts of tepid water. Several adjuncts, such as hypoa allergic-genic liquid soap, may be helpful. Other adjuncts, including hard brushes and dilute additives such as bleach, are unlikely to provide additional benefit and, in some scenarios, could be harmful. Contaminated clothing and special items such as valuables and firearms should be labeled and securely contained to prevent accidental or continued secondary contamination, as well as for possible forensic analysis during a HAZMAT or criminal investigation.

SECURITY

Security personnel at health care facilities should be engaged promptly because their primary responsibility is to protect existing patients, staff, and the health care facility from contamination and distraction from avoidable crowds by controlling all access points to the facility. This responsibility may entail limiting visits from arriving friends, family, and other third parties, as well as sequestering contaminated patients.

Security personnel should control traffic flow to and within the facility. Incoming patients should be directed to designated triage and decontamination sites, and the arrival of hospital personnel should be expedited. Patients awaiting further evaluation and disposition may be directed to secondary triage, holding, and treatment areas. Security personnel should coordinate with law enforcement and government agencies, safeguard valuables, and maintain the chain of custody of firearms and forensic evidence.

NERVE AGENTS

PATHOPHYSIOLOGY

Nerve agents are potent anticholinesterases that can be divided into three categories: quaternary ammonium alcohols, carbamates, and organophosphates. Quaternary ammonium alcohols are used as disinfectants. Carbamates are found in household insecticides. Also in insecticides, some organophosphates have been designed for use as warfare agents. The G series consists of tabun (GA), sarin (GB), soman (GD), and cyclosarin (GF). The V series, which includes VE, VG, VM, and VX, was developed 20 years later and is more potent and persistent, which means that it is not removed as easily.

Absorbed through inhalation and skin contact, nerve agents irreversibly bind and inactivate acetylcholinesterase (AChE) receptors, thereby leading to excessive accumulation of acetylcholine and overstimulation of nicotinic and muscarinic receptors. Though dose dependent, the effects from inhalation begin within seconds and peak within minutes, whereas the effects from skin exposure may take minutes to hours to become evident.

PRESENTING SIGNS AND SYMPTOMS

The earliest symptoms from inhalation are rhinorrhea and dim vision secondary to miosis, and those from skin contact are anxiety and fasciculations. With greater exposure, the classic symptoms of a cholinergic crisis become apparent. Hyperactivity of muscarinic receptors leads to lacrimation and salivation, bronchoconstriction, and vomiting and diarrhea. Hyperactivity of nicotinic receptors produces diaphoresis, tachycardia, hypertension, and muscle weakness. With severe or prolonged exposure, end-organs fatigue and fail, and convulsions, incontinence, flaccid paralysis, and apnea ensue.

TREATMENT

Atropine and pralidoxime chloride (2-PAM chloride) should be administered rapidly. When intubating patients, use of su cinylcholine should be avoided. Atropine, a competitive cholinergic blocking agent, can mitigate muscarinic symptoms and should be administered every 5 to 10 minutes until

1183
The earliest symptoms begin within minutes, but some symptoms may not be manifested for hours.

**PRESENTING SIGNS AND SYMPTOMS**

For mustard agents, the earliest symptoms are irritation and burning of exposed areas, such as the eyes and upper airway. Subsequent symptoms include pruritus and erythema of the skin, especially warm, moist locations such as the axillae and groin. With higher doses or prolonged exposure, shortness of breath, bulla formation, and corneal damage develop. Vomiting, diarrhea, bone marrow suppression, and seizures are associated with severe exposure and imply a poor prognosis.

Exposure to lewisite also produces eye, lung, and skin symptoms, which unlike those with mustard agents, begin immediately. With severe exposure, increased capillary permeability can lead to substantial loss of intravascular volume and end-organ damage.

**TREATMENT**

Unless completed within minutes of exposure, decontamination will not prevent tissue and DNA damage. It can, however, reduce or prevent ongoing exposure and secondary contamination. Only lewisite has a specific antidote, the chelating agent British antilewisite (BAL). BAL can be toxic itself, may contain peanut oil, and thus should not be given to patients with peanut allergy.

Additional treatment is primarily supportive. Eye injuries should be managed with lubrication and ophthalmologic antibiotics. Respiratory injuries may require oxygen, bronchodilators, and ventilatory support. Skin injuries should be treated similar to thermal burns, including wound care, tetanus prophylaxis, analgesia, and intravenous fluids. However, although fluid loss from mustard agents is less than that associated with thermal burns, lewisite casualties may require aggressive fluid replacement.

**BLOOD AGENTS**

**PATHOPHYSIOLOGY**

Blood agents include cyanide and arsenic-based chemicals. Absorbed through inhalation, ingestion, and topical exposure, blood agents disrupt the mitochondrial cytochrome oxidase complex, thereby inhibiting intracellular oxygen use and aerobic metabolism. Cyanide is the most well-known blood agent and is often associated with a pungent odor described as bitter almond. Cyanide is widely used in many industries, such as mining and plastic manufacturing, and can be released during the combustion of numerous natural and synthetic material. It has also been identified as a likely agent for use by terrorists.

**PRESENTING SIGNS AND SYMPTOMS**

The earliest symptoms begin within seconds to minutes and may include dyspnea, dizziness, nausea, and anxiety. With greater exposure, generalized weakness, diaphoresis, cyanosis, and hypotension may be observed, and with severe or prolonged exposure, dysrhythmias and seizures may progress rapidly to respiratory failure and death.

**TREATMENT**

Treatment should be initiated immediately and presumptively based on prehospital information and clinical suspicion.

*Maximum recommended dose of 2 g.

---

Vesicating agents are highly penetrative oily substances that induce blister formation and include mustard agents and organic arsenicals. Mustard has a wide range of effects on the eyes, skin, lungs, nervous system, and bone marrow. It has been produced and stockpiled by multiple countries. Lewisite is an arsenical often combined with mustard, smells like geraniums, and is associated with renal failure and hepatic necrosis.

Absorbed through inhalation and topical contact, mustard agents are alkylating substances that damage DNA and nucleic acid synthesis. The mechanism of toxicity for lewisite is not known. Symptoms are dependent on the agent, as well as the severity and route of exposure. The effects of lewisite begin within seconds to minutes. DNA damage from mustard agents begins within minutes, but some symptoms may not be manifested for hours.
because diagnostic tests are not readily available. Traditionally, definitive treatment has been administration of the three components of the cyanide antidote kit: amyl nitrite, sodium nitrite, and sodium thiosulfate. Hydroxocobalamin, a precursor of vitamin B₁₂, has gained acceptance as another antidote because it can be used for prehospital management and has better safety and side effect profiles.²⁸⁻³⁰

**PULMONARY AGENTS**

**PATHOPHYSIOLOGY**

Pulmonary agents include phosgene and chlorine. Absorbed through inhalation and topical contact, pulmonary agents irritate and cause an inflammatory reaction of the peripheral and central airways. Phosgene is widely used in many industries, released during the combustion of foam plastics, and associated with the smell of newly cut grass. Chlorine is used widely in manufacturing and for purifying water and has its own distinctive odor. It was the first chemical warfare agent and has recently been involved in several large-scale disasters and terrorist attacks.²⁰⁻³¹

**PRESENTING SIGNS AND SYMPTOMS**

Symptoms begin within minutes and may start with eye irritation, rhinorrhea, coughing, and dyspnea. With greater exposure, skin irritation, vomiting, and shortness of breath may be observed, and with severe exposure, blistering and pulmonary edema may develop.²²

**TREATMENT**

Treatment is primarily supportive. Eye injuries should be managed with ophthalmologic antibiotics and follow-up. Skin injuries should be treated similar to thermal burns, including wound care, tetanus prophylaxis, and analgesia. Respiratory injuries may require oxygen, bronchodilators, and endotracheal intubation and ventilatory support. Corticosteroids are recommended, and nebulized lidocaine and sodium bicarbonate may be beneficial.³¹

---

**Radiologic and Nuclear Agents**

**PATHOPHYSIOLOGY**

Radiation, regardless of type, causes injury through the production of charged water molecules and ionization of DNA. Because of its cellular effects, radiation can affect every organ, especially the hematopoietic, gastrointestinal, and central nervous systems.

Irradiation and external contamination by a radiologic agent may occur as a result of the surreptitious placement of a radiation emission device or detonation of a dirty bomb.³²⁻³⁴

A dirty bomb involves the use of conventional explosives to disperse radioactive material, such as iodine 131. After decontamination, treatment of blast injuries should precede treatment of radiologic injuries because immediate death from the radiation is unlikely³⁵⁻³⁶ (Table 137.2). If free of particulate matter and shrapnel, patients are unlikely to pose a significant threat to other patients and medical personnel.

Irradiation and external contamination by a nuclear agent may occur during transportation of HAZMAT or a nuclear reactor accident. Though an unlikely scenario, detonation of a nuclear device would involve catastrophic levels of radiation.

**PRESENTING SIGNS AND SYMPTOMS**

Within a few hours of exposure to greater than 1 Gy, three acute radiation syndromes may develop. Hematopoietic syndrome results in pancytopenia and a predisposition to infection, bleeding, and poor wound healing. Gastrointestinal syndrome results in abdominal cramping, vomiting, and diarrhea. Early intractable vomiting and bloody diarrhea imply a poor prognosis. Cerebrovascular syndrome results in confusion, ataxia, and seizures.³⁷

**TREATMENT**

After blast injuries and emergency medical conditions are treated, several radiation exposure-specific treatments should be discussed and initiated under the guidance of radiation safety, nuclear medicine, and hematology consultants. Any necessary surgeries should be performed within the first 24 to 36 hours before patients become immunologically incompetent. Cytokine therapy and the administration of chelating or blocking agents, such as potassium iodide and Prussian blue, should be considered.³⁷
Patients with the mildest of exposure to a chemical or radiologic or nuclear agent may be eligible for discharge after confirmation of the agent and consultation with an appropriate HAZMAT expert. However, because the majority of chemical and radiologic or nuclear agents are associated with prolonged symptoms and delayed effects, most patients should be admitted. Patient disposition should also be coordinated with responding law enforcement and government agencies for possible interview during a HAZMAT or criminal investigation.

Mammalian Bites

Ashley Booth Norse

Dog bites are the most common mammalian bites seen in the ED. Dog bites tend to cause more damage, injure deeper structures, and crush tissues because of the animal’s powerful jaws, which can exert a pressure of 200 to 450 psi when biting. ¹ Damage to deeper structures is more common with police dogs.² Dogs trained specifically for guard duty or for fighting, such as pit bulls, rottweilers, German shepherds, and chows, tend to cause a disproportionate number of bites resulting in serious injury and death.³

Current research reveals that Pasteurella species are the most common organisms present in culture isolates from infected dog bite wounds, most frequently Pasteurella canis.⁴ Other common aerobic pathogens in infected dog bite wounds include Staphylococcus and Streptococcus species.⁵ Aerobes less frequently associated with cat and dog bite wound infections include Moraxella and Neisseria. Causative anaerobic organisms include Fusobacterium, Bacteroides, Porphyromonas, Prevotella, and Capnocytophaga. Capnocytophaga canimorsus causes an opportunistic infection that can result in severe infection and sepsis in immunocompromised patients. Mortality in patients with C. canimorsus infection approaches 30%.⁶

When compared with cat bite victims, patients with dog bites tend to be seen later after injury but have a lower infection rate. Conversely, patients whose injuries become infected secondary to cat bites tend to seek treatment earlier than those with infected dog bite wounds, at a mean time of 12 hours.¹ It is speculated that the infection rate is higher because wounds from cats are more likely to be punctures, involve the hand, and become infected with Pasteurella species.¹

Human bites have long been associated with high rates of infection and complications such as septic joints, osteomyelitis, tenosynovitis, and fractures. However, recent studies show that human bites do not have a higher rate of infection than other bite wounds do.¹,⁴,⁵

Human bites can be divided into two categories. The first category is referred to as occlusional bites, defined as intentional bites in which the teeth actually close down on the victim’s skin. The second category is referred to as clenched-fist injuries (also called “fight bites”); these bites occur when the teeth hit or puncture the dorsum of the metacarpophalangeal region of a clenched hand. Clenched-fist injuries have a high propensity for causing injury to deep structures of the hand. Open fractures, joint involvement, and tendon injuries are common. Human bites to the hand, especially clenched-fist injuries, are at high risk for infection.²,⁴,⁵

### KEY POINTS

- Human bites, especially clenched-fist injuries (i.e., “fight bites”) commonly cause septic joints, osteomyelitis, tenosynovitis, and fractures.
- Wound infections caused by human bites are usually polymicrobial.
- Pasteurella species are the most common organisms present in infected wounds from cat and dog bites.
- Injury to deeper structures should be suspected with all mammalian bites, and radiography should be considered to look for fractures, retained foreign bodies, gas in tissues, and osteomyelitis.

### EPIDEMIOLOGY

Two to 4 million cat, dog, and human bites are reported by the Centers for Disease Control and Prevention every year, as well as approximately 300,000 emergency department (ED) visits secondary to mammalian bites. The exact number of mammalian bites is difficult to determine because many cases are not reported. Although dog bites outnumber cat bites, 20% to 80% of cat bites become infected, whereas just 3% to 18% of dog bites will become infected.¹-⁴

### PATHOPHYSIOLOGY

Wound infections from mammalian bites have a complicated microbiology profile. The majority of infections are polymicrobial with a mix of aerobic and anaerobic bacteria. Patients with acute cat bites (<24 hours from the time of the bite) most often have wound cultures that grow Pasteurella organisms, especially Pasteurella multocida. Patients with subacute cat bites (>24 hours) or who return to the ED more than 24 hours after initial treatment of an acute bite typically have cultures that grow mixed aerobic and anaerobic species, with Pasteurella, Staphylococcus, and Streptococcus species being the predominant pathogens. Other pathogens include the aerobe Moraxella and the anaerobes Fusobacterium, Bacteroides, and Porphyromonas.²,³,⁵,⁶
**Table 138.1 Pathogens in Mammalian Bites**

<table>
<thead>
<tr>
<th>MAMMALIAN BITE</th>
<th>&lt;24 HOURS</th>
<th>&gt;24 HOURS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Human</td>
<td>Polymicrobial: <em>Streptococcus</em> spp., 60-80% <em>Staphylococcus</em> spp., 37-46% <em>Anaerobic</em> spp., 44-60% (specifically <em>Eikenella corrodens</em>, 20-25%)</td>
<td>Mixed aerobic and anaerobic <em>Streptococcus</em> spp., <em>Staphylococcus</em> spp., <em>Cutaneous</em> spp., <em>Streptococcus</em> spp.</td>
</tr>
<tr>
<td>Cat</td>
<td><em>Pasteurella</em> spp.</td>
<td>Mixed aerobic and anaerobic <em>Pasteurella</em> spp., <em>Staphylococcus</em> spp., <em>Streptococcus</em> spp.</td>
</tr>
</tbody>
</table>

Wound infections caused by human bites are usually polymicrobial. *Streptococci* are present in 60% to 80% of isolates. *Staphylococcus aureus* is found in 37% to 46% of isolates, and anaerobic species are present in 44% to 60% of isolates, specifically *Eikenella corrodens* (20% to 25%). Herpes simplex virus can also be transmitted through infected saliva and can cause herpetic whitlow, as well as wound infections (Table 138.1).²

**PRESENTING SIGNS AND SYMPTOMS**

A thorough history should be obtained (Fig. 138.1), including the timing of the bite incident, the circumstances surrounding the bite, and whether a report was filed with animal control officials. If the victim knows the animal, it may be possible to ascertain the immunization status of the bite source and whether the animal is going to be quarantined to observe for signs of rabies. This information is especially important if the bite was unprovoked, if the animal was acting abnormally, or if the bite was caused by a wild animal. The patient’s medical history (including a history of allergies, current medications, and immunization status) should also be obtained.

Patients with human bites, especially clenched-fist injuries, may not be forthcoming about how their injury occurred. If the wound is on the extensor surface of the metacarpophalangeal joint, the patient should be treated as though the wound is a human bite. In patients with human bites, it is important to ascertain the human immunodeficiency virus (HIV) and hepatitis status of both the patient and the attacker.

In major cases in which a patient suffers extensive injury, resuscitation from traumatic injury may be needed. Injury to deep structures, including major organs, and extensive blood loss are possible. It is usually apparent that a large animal has attacked the victim, but injuries from falls or other associated trauma can occasionally be occult. Disciplined, thorough evaluation of the patient’s physical condition is warranted when associated injury may have occurred, especially since bite wounds draw the clinician’s attention.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Vital signs should be determined in all patients with bites because hypotension or tachycardia may be a sign of blood loss and fever may be a sign of infection. All bites mandate a full neurovascular examination, including a thorough motor and sensory examination distal to the bite, as well as evaluation of all the tendons and ligaments in the region of the bite. The physical examination should also include a thorough vascular examination and evaluation of any compartments involved.

**RED FLAGS**

Emergency medical physicians must have a high level of suspicion with mammalian bites.

For clenched-fist injuries, a high index of suspicion should be maintained for tendon injuries, as well as for open fracture and open joints. The metacarpophalangeal joint and extensor tendons are covered by a thin layer of skin when the hand is clenched, and tendons can often retract proximally when the hand is unclenched and the fingers extended.

All bite wounds should undergo high-pressure irrigation of the wound with normal saline, dilute povidone-iodine solution, or poloxamer 188 (Shur-Clens). Explore all wounds. Extend the margins of deep puncture wounds or small laceration so that all possible injured structures can be visualized if possible injury to deeper structures is suspected.

Radiography, angiography:

- If there is risk for a retained foreign body such as a tooth
- If there is risk for injury to deep structures such as a fracture
- If the patient has signs of infection (to look for retained foreign bodies, gas in tissues, and osteomyelitis)
- If a vascular injury is suspected, angiography may be needed to localize the injury or to determine the extent of the injury

**TREATMENT**

All bite wounds should undergo high-pressure irrigation of the wound with normal saline, dilute (<1%) povidone-iodine solution, or poloxamer 188 (Shur-Clens) (Table 138.2). Recent studies have looked at the efficacy of tap water as an irrigation solution; however, because no conclusive data exist at present for bite wounds, use of tap water as an irrigation solution for bite wounds cannot be supported at this time. Patients with larger or more complicated wounds may need to be anesthetized with lidocaine, bupivacaine, or another...
anesthetic agent before irrigation and exploration of the wound. Epinephrine should be avoided if the bite involves the fingers, toes, nose, ears, or penis.²

All wounds should be explored for foreign bodies and injuries to deeper structures such as arteries, nerves, tendons, and ligaments. All tendons in the injured area should be isolated and tested through their full range of motion to assess for partial lacerations or tears, especially if the hands or feet are involved. Any devitalized tissue or ragged edges should be débrided.

There is no clear evidence whether suturing bite wounds increases the risk for infection, nor are there conclusive data on which wounds can safely be sutured. The safest course of action is to leave most bite wounds open and have the patient return for delayed primary closure if the wound does not become infected; however, primary closure may be necessary for cosmetic or functional reasons.

Recent studies show that the infection rate of sutured bite wounds may initially be lower in certain circumstances than historically predicted. Primary closure may be safe for simple bite wounds less than 6 hours old that involve the trunk and extremities (with the exception of the hands and feet) and for simple bite wounds involving the face and neck that are less than 12 hours old.¹²

The emergency physician should leave wounds open or consider closure by secondary intention for all infected wounds and all wounds at increased risk for infection, such as puncture wounds, hand and foot wounds, clenched-fist injuries, full-thickness wounds, wounds requiring débridement, wounds in patients older than 50 years or immunocompromised patients, wounds more than 12 hours old, and wounds involving damage to deep structures such as bones, joints, tendons, nerves, and blood vessels. Extremity wounds should be splinted and elevated.²

All patients sustaining mammalian (cat, dog, human, primate) bites should be given a dose of tetanus immune globulin and a dose of tetanus toxoid if they have never had the tetanus vaccine series or if they have not had three doses of tetanus toxoid. Patients who have had a full course of the tetanus vaccine series should be given a tetanus toxoid booster of 0.5 mg intramuscularly if more than 5 years has elapsed since the previous tetanus booster.

HAART, Highly active antiretroviral therapy; HBIG, hepatitis B immune globulin; HBV, hepatitis B vaccine; HIV, human immunodeficiency virus; HRIG, human rabies immune globulin; IM, intramuscularly; Pr., prophylaxis.
Patients who sustain dog, cat, or other animal bites should be evaluated for the potential need for rabies vaccination (see Chapter 179). Patients who sustain high-risk bites in which the animal cannot be quarantined should receive 20 IU/kg of human rabies immunoglobulin (HRIG) injected around the bite site or intramuscularly (or both) and 1 mL of rabies vaccine administered intramuscularly either in the deltoid in adults or in the thigh in children on days 0, 3, 7, 14, and 28. HRIG and rabies vaccine should be injected at separate sites if both are administered intramuscularly.

Transmission of HIV and hepatitis B and C virus in human bites has been reported. Patients who sustain human bites need to be evaluated and counseled about HIV and hepatitis B postexposure prophylaxis (PEP) (PEP for hepatitis C does not exist). HIV PEP should be started as soon as possible within the first 48 to 72 hours after a high-risk bite and continued for 28 days. High-risk bites are those in which the assailant is known to be HIV or hepatitis positive (or both) and bites in which blood exposure is involved. Hepatitis B PEP should include hepatitis B immune globulin (HBIG) and hepatitis B vaccine (HBV) if the patient has not previously been immunized. If the patient had previously received the hepatitis B vaccination series, a titer for anti-HBV should be drawn. If the patient has hepatitis B antibodies, no treatment is needed; if there are insufficient antibodies (anti-HBV < 10 mIU/mL), the patient needs HBIG and an HBV booster.

Clinical evidence is limited on which cat and dog bites should receive prophylactic antibiotics. Cat bites—especially puncture wounds, wounds involving the hand and feet, wounds involving deeper structures, wounds in immunocompromised patients, and wounds closed primarily—are considered high-risk bites, and the patient should receive prophylactic antibiotics. Prophylactic antibiotics for cat and dog bites, specifically those seen within the first 24 hours, should cover Pasteurella, Staphylococcus, Streptococcus, and anaerobic species. Options include amoxicillin-clavulanate, a second-generation cephalosporin with anaerobic activity, and penicillin plus a first-generation cephalosporin. Clindamycin plus a fluoroquinolone or trimethoprim-sulfamethoxazole may be used in penicillin-allergic patients. Doxycycline plus metronidazole can also be used in penicillin-allergic patients.

Human bites are also considered high-risk bites. Prophylactic antibiotics should be considered for bites extending through the dermis, bites closed primarily, bites with significant crush injury or requiring considerable débridement, puncture wounds, bites in elderly or immunocompromised patients, and bites that involve the hands, feet, or deeper structures. Human bite prophylaxis should cover Staphylococcus, Streptococcus, and anaerobes, including E. corrodens. Amoxicillin-clavulanate or penicillin plus dicloxacillin may be used. Clindamycin plus ciprofloxacin or trimethoprim-sulfamethoxazole may be used in penicillin-allergic patients.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Wounds with significant tissue loss may need plastic surgery or hand surgery consultation for skin grafting, depending on the location of the bite. Specialty consultation is also mandated for any hand or foot wound that involves a joint, tendon, artery, or nerve. Most patients can be discharged home safely with follow-up or recheck in the ED, or both.

Venomous Snakebites in North America

Robert L. Norris

KEY POINTS

- Mortality following venomous snakebites in the United States is less than 1%, especially when patients are treated with antivenom.
- Permanent local sequelae following pit viper bites occur in at least 10% of patients.
- No field management (first aid) measure has been proved to be effective for pit viper bites other than expeditious transport to definitive medical care.
- The key to management of a venomous snakebite is judicious and timely use of antivenom.
- Hypotensive victims of snakebite are treated with antivenom and intravenous fluids; vasopressors are a last resort.
- All patients with a suspected venomous snakebite who have any signs or symptoms of envenomation are admitted to the hospital.
- Fasciotomy is rarely needed following pit viper bites and is performed only in the setting of objectively documented compartment syndrome.

PATHOPHYSIOLOGY

Snake venom, particularly pit viper venom, is a complex mixture of enzymes, low-molecular-weight (nonenzymatic) proteins, metallic ions, and other constituents. \(^5,^6\) The venom is highly variable, depending on the species of snake; its geographic origin; its age, health, and diet; and the time of year. \(^6\) Among the most important components found in pit viper venom are phospholipase A\(_2\) enzymes, which cause cellular disruption and tissue damage; hyaluronidase, which facilitates the distribution of venom within tissues; and thrombin-like enzymes, which affect various aspects of the coagulation cascade and lead to coagulation abnormalities.

Also of major importance in pit viper venom–induced coagulopathy are metalloproteinases known as hemorrhagins, which increase vascular permeability and damage endothelial cells. \(^7,^8\) Some rattlesnakes, such as certain specimens of Mohave rattlesnakes (Crotalus scutulatus), possess neurotoxic components in their venom. These presynaptically acting toxins prevent the release of acetylcholine at neuromuscular junctions. Depending on their geographic location, Mohave rattlesnakes may possess this component and are termed venom A–producing rattlesnakes. \(^5,^10\)

Other rattlesnakes that may, based on their geographic origin, possess neurotoxic components closely related to Mohave toxin include the eastern diamondback rattlesnake (Crotalus adamanteus), the timber rattlesnake (Crotalus horridus), the southern Pacific rattlesnake (Crotalus oreganus helleri), and the tiger rattlesnake (Crotalus tigris). \(^11-15\)

Coral snake venom is less complex than pit viper venom but is among the most toxic venom in North America. The primary effects of coral snake venom are neurotoxic and are due to a component in the venom that blocks the postsynaptic end plates at neuromuscular junctions. \(^16,^17\)

ANATOMY

Pit vipers get their name from the sensitive heat receptors (foveal organs) located on the anterior of their heads, slightly below and between the nostril and eye (Fig. 139.1). These organs aid the snake in finding prey, aiming its strike, and determining the volume of venom to be injected. Other characteristics typical of a pit viper include a triangular-shaped...
head (also found in many nonvenomous snakes), elliptical (catlike) pupils, and in the United States, the presence of a single row of scales that spans the underside of its tail (Fig. 139.2). Nonvenomous snakes in the United States generally have a double row of scales crossing the ventral aspect of the tail. Rattlesnakes can also usually be identified by the keratin plates that make up their unique caudal rattle.

Pit vipers range in size from the diminutive pygmy rattlesnake (*Sistrurus miliarius*), typically 40 to 50 cm in length, to the massive eastern diamondback rattlesnake (*Crotalus adamanteus*), which can attain lengths of greater than 1.5 m (Fig. 139.3).18 Coral snakes are identified in the United States by their characteristic color pattern—red, yellow, and black bands that completely encircle the body, with the red and yellow bands

![Image](image-url)
being contiguous. In harmless coral snake mimics, such as milk snakes (*Lampropeltis* spp.), the red and yellow bands are separated by a band of black (Fig. 139.4). Color patterns cannot, however, be used outside the United States to reliably identify coral snakes.

Venomous snakes possess venom-producing glands in the upper jaw, behind the eyes (Fig. 139.5). These glands produce the venom that at the time of a bite is passed via ducts to the hollow, needle-like fangs on the anterior maxillae. In pit vipers, these fangs range in length (proportional to the snake’s overall length) from just a few millimeters to more than 2.5 cm. The fangs are folded up against the roof of the snake’s mouth when not in use. During a bite, the pit viper opens its mouth widely and swings its fangs into an upright position to drive them into the tissues of its target. Venom is then injected via a set of investing musculature. The speed of a pit viper’s strike has been clocked at 8 feet per second—faster than a human being can react.

The venom delivery apparatus of a coral snake is less sophisticated than that of a pit viper. Coral snakes have slightly enlarged, anterior, maxillary fangs fixed in an erect position, with which they inject venom (Fig. 139.6). For a coral snake to produce envenomation, it must chew on its victim for a few seconds. Bites by coral snakes frequently involve someone.
intentionally picking the snake up, often after misidentifying it as a harmless snake. \(^\text{20}\)

**PRESENTING SIGNS AND SYMPTOMS**

The signs and symptoms of pit viper envenomation are broken down into local and systemic findings. Locally, the victim will have puncture wounds, although the pattern may be misleading and cannot be used to reliably differentiate between a venomous bite and a bite by a harmless snake. Generally, severe, burning pain develops at the bite site within minutes, followed shortly by local swelling that can progress over time to involve the entire bitten extremity and even the trunk. There may be persistent bloody oozing from the fang marks, indicative of coagulopathy. Ecchymosis may be present at the site and, more remotely, as hemorrhagins induce vascular leaks and loss of red blood cells, in tissues (Fig. 139.7). Over several hours to days, blisters and blebs may form on the extremity, particularly at the bite site. These lesions are filled with clear serous fluid or bloody exudate.

Systemically, victims have a myriad of complaints, which can include nausea, vomiting, and dizziness; numbness of the mouth, tongue, or extremities; muscle fasciculations (myokymia); and shortness of breath. The victim’s vital signs may be abnormal. Patients with severe bites may be tachycardic and hypotensive.

In the early stages, hypotension is due to systemic vasodilation. Later, the hypotension is compounded by third spacing of fluids into the bitten extremity and potentially hemolysis. \(^\text{15}\)Some pit vipers, such as venom A–producing Mohave rattlesnakes, may produce few local signs and symptoms but may cause more systemic toxicity, particularly neurotoxic findings such as ptosis and difficulty swallowing and breathing.

Bites by a coral snake generally cause little in the way of local findings, and their fang marks may be difficult to see. \(^\text{21}\)Swelling is usually slight and pain is variable (mild to more pronounced). Victims of significant bites by a coral snake may have a delay in the onset of systemic findings, sometimes for many hours. \(^\text{22}\)Signs of neurotoxicity may then develop, with the earliest findings being altered mental status and cranial nerve dysfunction (e.g., ptosis). Neurotoxicity can progress to frank skeletal muscle paralysis and respiratory failure.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis in a snakebite victim is generally limited. Most often the victim can recount being bitten by a snake. On rare occasion the victim may not have seen a snake, as when walking through high grass when bitten. In such cases, the presence of at least one puncture wound and progression of local and systemic findings are usually diagnostic. If the victim saw the snake but cannot adequately describe it, careful observation over time will reveal whether envenomation has occurred. Having color photographs on hand of the snakes found locally can aid in proper identification of the offending reptile.

Victims bitten by a coral snake almost always see the snake because of its need to actually chew on them to produce a significant bite. When a coral snake is implicated, the difficulty may be in differentiating the snake as a true coral snake versus a harmless coral snake mimic. Here again, color photos may help if the victim can recall the color pattern of the animal. All victims of a potential bite by a coral snake are observed carefully for at least 24 hours in the hospital because of the possible delay in onset of toxicity.

Young children have no innate fear of snakes and may be unable to describe precisely what bit them, particularly if they are preverbal. All children with possible venomous snakebites are admitted to the hospital for monitoring for at least 24 hours.

**DIAGNOSTIC TESTING**

In the initial phase of evaluating a victim of a potential pit viper bite, a complete blood count and coagulation studies are repeated every 1 to 2 hours as long as the findings are normal (Table 139.1). If an abnormality appears (e.g., diminished platelets or fibrinogen), antivenom should be administered (see later) and laboratory tests rechecked every 6 hours thereafter until stable. This 6-hour period after antivenom administration is necessary for a healthy liver to replete coagulation factors.

**TREATMENT**

**PREHOSPITAL MANAGEMENT**

Field management focuses on providing reassurance and rapid transport to a facility equipped with antivenom. If possible to do so safely, the snake is identified. No attempt should be made to capture or kill the snake, although it may be possible to photograph the animal if a digital camera is available.

No first aid measures have ever been proved to be beneficial in victims of pit viper bites. For victims bitten by a coral snake, the Australian pressure-immobilization technique is applied quickly in the field to limit the spread of venom. This involves wrapping the entire bitten extremity snugly in an occlusive wrap followed by the application of a splint (Fig. 139.8). Victims must then be carried from the field for the

![Fig. 139.7 Extensive ecchymosis several days after a bite by a northern Pacific rattlesnake (*Crotalus oreganus oreganus*) on the victim’s pretibial region. (Photo © Dr. Robert L. Norris.)](image_url)

HOSPITAL MANAGEMENT

Hospital management of snakebite victims begins with assessment of respiratory and circulatory status. The patient is initially administered oxygen, and cardiac and pulse oximetry monitoring is begun while the emergency physician takes a directed history and performs a focused physical examination. It is uncommon for snakebite victims in North America to initially be seen with significant respiratory compromise. In patients bitten by coral snakes or rattlesnakes with neurotoxic venom, however, difficulty with airway patency and breathing can develop.

If signs of neurotoxicity are present and any shortness of breath or difficulty speaking or swallowing develops, the airway should be promptly and definitively secured by endotracheal intubation to prevent aspiration. If the victim shows any signs of dehydration or shock, fluid resuscitation is begun with the administration of 1 to 2 L of normal saline (20 to 40 mL/kg for children). If the blood pressure does not respond promptly to crystalloid infusion, albumin is added because it may remain in the leaky vasculature for a longer period. Vaspressors are used only as a last resort after adequate intravascular volume repletion has been achieved. Inadequately treated hypotension is a key aspect in many cases of fatal snake envenomation.

Once the ABCs (airway, breathing, and circulation) have been addressed, an attempt is made to identify the offending snake. If the victim has brought the snake to the hospital, extreme caution should be used in examining it, even if it appears to be dead. A severed snake head can have a bite reflex for up to an hour following death and is capable of inflicting a serious bite.

Circumferences of the bitten extremity are marked and measured at the bite site and at one or two sites more proximally every 15 minutes during the early stages of envenomation. This offers an objective measure of the progression of local swelling. If the circumferences are increasing, the envenomation is progressing and administration of antivenom is indicated.

The key to management of significant envenomation is antivenom administration. Initial decisions on antivenom administration are guided by the clinical findings (Box 139.1).

Pit Viper Antivenom

The current antivenom available in the United States for pit viper bites, Crotalidae polyvalent immune Fab, ovine (CroFab; BTG International, Inc., West Conshohocken, PA), is produced by immunizing sheep with the venom of four different pit vipers. The ovine IgG antibodies obtained are further refined by digestion with papain to yield Fc and Fab fragments. The Fc fragments—responsible for inducing many acute anaphylactoid reactions to antivenom—are discarded, and the protective Fab fragments are isolated with affinity column chromatography. CroFab is packaged in a lyophilized state and requires reconstitution before administration.

Antivenom administration is described in detail in Box 139.2 and in the Tips and Tricks box. Antivenom is effective in reversing most systemic and laboratory derangements seen following snake envenomation. However, its ability to reverse thrombocytopenia, rhabdomyolysis, or myokymia is variable. Antivenom’s efficacy in preventing local tissue damage has never been definitively demonstrated. If given very early in the course, it may reduce or limit permanent local damage to some slight degree.

Coral Snake Antivenom

At the time of this writing, production of coral snake antivenom has ceased in the United States, with the current remaining stock set to expire October 31, 2012. Coral snake antivenom is still produced in Mexico (Coralymn, Instituto Biocon), but it is not commercially available in the United States. There is reportedly a plan in place for Pfizer to resume production of Micrurus antivenom in the United States.
Even though the onset of neurotropic findings following a bite by a coral snake may be delayed, once they start, they may be rapidly progressive and relatively unresponsive to antivenom administration. Management of a victim of a serious bite by a coral snake (definitively identified *Micrurus* specimen, particularly *M. fulvius*, and effective penetration of the fangs into the victim’s skin) ideally includes prompt administration of antivenom before evidence of neurototoxicity begins. In the absence of appropriate coral snake antivenom, these victims must be managed conservatively, including securing the airway at the first sign of difficulty swallowing or breathing and providing mechanical ventilation (possibly for many days). If appropriate antivenom is available, it should be administered according to the manufacturer’s guidelines, and all the precautions outlined for administration of pit viper antivenom should be taken (see Box 139.2). Pit viper antivenom is of no benefit to victims of bites by a coral snake.

No antivenom is available for Sonoran coral snake (*M. euryxanthus*) bites, but this species is quite small and inoffensive and has never caused a known fatality. Management is purely supportive.

**Other Treatment Considerations**

Blood products are rarely needed for victims of venomous snakebites, even with significant coagulopathy noted on laboratory tests. Aggressive antivenom administration always precedes the administration of any blood products to avoid feeding further substrate to an ongoing venom-induced consumptive coagulopathy.

Wound management of pit viper bites includes placing the extremity in a well-padded splint and elevating it above heart level to reduce swelling. Tetanus prophylaxis is given if needed. Prophylactic antibiotics are not necessary unless misdirected first aid measures included incisions into the bite wound or mouth suction. In such cases, a broad-spectrum antibiotic (to cover both gram-positive and gram-negative bacteria) is administered in standard doses. Pit viper bites in the United States rarely become infected. When they do, however, antibiotic therapy is guided by wound culture testing. Tissue that is clearly necrotic is débrided after the patient is stabilized and once any attendant coagulopathy has been reversed. Intact blebs and blisters are left undisturbed, and those that rupture are conservatively unroofed. Physical therapy is started as early as possible to return the patient to an optimal level of functioning.

Indications for obtaining any consultations that may be needed are listed in Box 139.3.
BOX 139.3 When to Consider Consulting a Snakebite Expert*

The treating physician is uncomfortable evaluating or managing snakebite victims.
The envenomation is clearly severe (e.g., victim in respiratory distress, requiring intubation, or in shock).
The victim is pregnant.
The victim has significant underlying comorbid conditions (e.g., coronary artery disease, severe pulmonary disease).
No appropriate antivenom is available.
The victim has an acute adverse reaction to antivenom.
Recurrent coagulopathy is noted on follow-up evaluation.

* A regional poison control center can be reached in the United States at 1-800-222-1222.

BOX 139.4 Management of Acute Reactions to Antivenom (Allergic or Nonallergic Anaphylaxis)

Immediately stop the infusion.
Treat the signs and symptoms in standard fashion (airway management as needed, epinephrine, crystalloid infusion, antihistamines [H1 and H2 blockers], steroids, and vaso-pressors as needed).
In most cases the antivenom can be restarted (with the emergency physician at the bedside) once the reaction abates.
If the reaction was severe and appears more life-threatening than the envenomation, a decision may be made to withhold further antivenom therapy. It is very helpful to consult an expert on snake envenomation in such cases.

NEXT STEPS: ADMISSION AND DISCHARGE

All patients with any evidence of envenomation are admitted to the hospital for further observation and management. If the envenomation is severe, the victim is admitted to an intensive care unit. If it appears that the snake did not inject any venom (i.e., a dry bite—no signs or symptoms of envenomation, simple puncture wounds only), the victim is observed in the emergency department for a minimum of 8 hours. After 8 hours, victims who remain asymptomatic, with normal vital signs and laboratory results, are discharged in the care of a responsible adult and told to return if any evidence of envenomation occurs. Dry bites occur in as many as 20% of pit viper bites, although the precise reason for this remains unclear. Any child with a possible venomous snakebite is admitted to the hospital regardless of the presence or absence of signs or symptoms of poisoning. Likewise, victims of a possible bite by a coral snake are admitted for observation because of the significant delay that can occur before any evidence of envenomation is apparent.

DOCUMENTATION

Record a careful history in the patient’s own words, including a description of the snake.
Record the results of a thorough screening physical examination.
Have nursing staff measure and record the circumferences of the bitten extremity every 15 minutes until the swelling has stabilized and then every hour for 24 hours.
Note the specifics of any discussion with consultants (e.g., poison control specialists).
Measure and record intracompartmental pressures if concern arises about the development of compartment syndrome.
Document informed consent (for antivenom administration or fasciotomy) if possible.

COMPLICATIONS

ADVERSE REACTIONS TO ANTIVENOM

Adverse reactions to antivenom include early, acute reactions (which are probably anaphylactoid in nature [also known as nonallergic anaphylaxis]) and delayed serum sickness, an immunoglobulin (IgG and IgM) immune complex–mediated disease. Anaphylactoid reactions may be manifested as hives, wheezing, laryngeal edema, abdominal pain, vomiting, diarrhea, and hypotension. The incidence of anaphylactoid reactions to CroFab is approximately 15%, with most reactions being minor and easily treated (Box 139.4). Serum sickness occurs in approximately 3% of patients treated with CroFab and may be manifested approximately 1 to 2 weeks after administration as fever, urticaria, myalgia, arthralgia, renal dysfunction, or neuropathy (or any combination of these signs). Serum sickness is easily treated with oral steroids (e.g., prednisone, 1 to 2 mg/kg orally per day) administered until the symptoms resolve, followed by a 2-week tapering of the dose. Oral antihistamines may provide additional symptomatic relief. Before discharge from the hospital, patients are warned to watch for signs and symptoms of serum sickness and told to return if they occur.

COMPARTMENT SYNDROME

Some larger rattlesnakes have fangs long enough to penetrate deeply into muscle compartments. Because many significant pit viper bites result in swollen extremities that are discolored and painful on any attempted range of motion, it can be difficult to determine when a compartment syndrome is imminent. This complication is actually rare following pit viper bites, but if there is concern about rising intracompartmental pressure, it is objectively measured with any standard technique. If the pressure is elevated above 30 to 40 mm Hg, the limb is further elevated, more antivenom is administered, and mannitol is given (1.0 g/kg intravenously over a 30-minute period) if the patient is hemodynamically stable. If the compartment pressure remains high 1 hour after these measures have been carried out, fasciotomy is considered. Although animal research has suggested an actual increase in myonecrosis following fasciotomy, there is still a risk for ischemic...
neuropathy following unabated rises in compartment pressure. It is important to obtain informed consent, if possible, before proceeding with fasciotomy.

**RECURRENT COAGULOPATHY**

Patients in whom coagulopathy develops during the initial stages of pit viper envenomation may have delayed recurrence of abnormal coagulation studies for up to 2 weeks following the bite.\(^\text{20,21}\) This is probably related to continued absorption of venom components from the depot site after all antivenom administered has been cleared from the body, particularly when a low-molecular-weight Fab antivenom (e.g., CroFab) is used. In most cases, delayed coagulopathy is benign, without evidence of clinically significant bleeding, but severe complications, including intracranial bleeding, have been reported.\(^\text{46,47}\) Patients are warned of this possibility and instructed to avoid any elective surgery, contact sports, and other high-risk activities for a few weeks following the bite. Although administration of antivenom for delayed coagulopathy may be helpful, it is likely to be less effective than in the acute stages of envenomation. Reasonable indications for administering further antivenom in these cases are outlined in Box 139.5.

**PROGNOSIS**

Deaths attributable to bites by endemic snakes are rare in the United States, with only 33 reported to the American Association of Poison Control Centers in the 26-year period from 1983 to 2008.\(^\text{1}\) This is an underestimate of the total number of deaths because snakebite is not a reportable condition, but it does reflect the limited toll of snakebite in terms of loss of...
life in the United States. Deaths are even more infrequent in Canada, whereas in Mexico, as many as 150 people die each year of venomous snakebites. The case fatality rate following venomous snakebite in the United States when antivenom is used is less than 1%. However, long-term complications, such as loss of some degree of function in the bitten extremity, are more likely. Approximately 10% of victims will be left with some functional disability following pit viper bites, and this does not include permanent dysfunction directly related to surgical procedures. The incidence of disability may actually be higher if careful, delayed evaluation of extremity function is performed (e.g., using goniometry and precise sensory testing).

KEY POINTS

- Anaphylaxis, typically caused by Hymenoptera stings, is the most serious complication of all arthropod encounters and should be treated with steroids, epinephrine, and antihistamines when needed.
- Massive envenomations (>10 stings per kilogram or >100 stings per person) by Hymenoptera merit close monitoring for systemic effects of the venom.
- Latrodectism should be treated with adequate analgesia and benzodiazepines, but antivenom should be considered for severe cases.
- Dapsone, hyperbaric oxygen, colchicine, and electric shock therapy are no more effective than supportive care for the treatment of true dermonecrotic arachnidism.

EPIDEMIOLOGY

Arthropod venoms are complex mixtures of enzymes, proteins, histamines, and other bioamines that can either damage tissue directly or elicit an allergic response. The venoms of each family are unique, and cross-reactivity is rare with the exception of wasps, hornets, and yellow jackets (vespids). Local tissue reactions from dermal exposure to arthropod antigens result in the common pruritic, urticarial, and papular lesions seen after envenomation. The most immediately life-threatening complication of arthropod exposure is anaphylaxis either to the venom itself or to the antivenom administered in the ED. Treatment of anaphylaxis merits special discussion and is covered in the next section on Hymenoptera.

HYMENOPTERA

PATHOPHYSIOLOGY

Apidae (bees), Vespidae (wasps, yellow jackets, hornets), and Formicidae (ants) are the most clinically significant groups of arthropods for two reasons. First, the incidence of Hymenoptera venom allergy has been estimated to be 0.8% to 5% in the general population and is increasing, particularly in young people. Second, because of their complex social organization, multiple stings are more likely to occur during Hymenoptera encounters than with arthropods that do not build nests or hives.

Recent research indicates that the major allergens in Hymenoptera venom are phospholipases and hyaluronidases, as well as mellitin, a peptide that causes degranulation of mast cells. Hymenoptera venom is delivered via an ovipositor stinger and gland, although some anatomic variation does exist. Male bees have no stingers and are incapable of stinging when threatened. Females have barbed stingers that become lodged in human skin and eviscerate the bee after venom delivery. The retained stinger and venom sac can be removed with tweezers. Africanized “killer” bees deserve special mention in that (1) they are far more aggressive and territorial than the more docile domesticated varieties, (2) are known to pursue perceived threats for up to 1 km, and (3) do so in much larger swarms. Africanized bees are difficult to distinguish morphologically from domesticated bees, but fortunately, this distinction is of little clinical significance because of venom
Massive envenomations are considered those in which the victim sustains more than 100 stings or more than 10 stings per kilogram (Fig. 140.1). Such cases merit special respect and victims should be considered for admission because of an increased risk for systemic symptoms, including nausea, vomiting, diarrhea, edema, dyspnea, hypotension, and rhabdomyolysis. Rarely, glomerulonephritis, acute renal failure, and acute respiratory distress syndrome can occur.5-7

**DIAGNOSTIC TESTING**

No laboratory testing is necessary in cases limited to cutaneous symptoms from submassive envenomations. Massive envenomations or systemic reactions require investigation to evaluate for rhabdomyolysis, renal failure, or cardiac ischemia.5,6,8 Appropriate testing should include a basic chemistry panel and creatine phosphokinase (CPK) level.

**ANAPHYLAXIS AND ALLERGIC REACTIONS**

It has been estimated that 40 deaths occur per year in this country as a result of anaphylaxis from Hymenoptera stings. Anaphylaxis is an IgE-mediated type I hypersensitivity reaction that leads to mast cell and basophil degranulation of vasoactive mediators, cytokines, prostaglandins, and platelet-activating factor. Some initial symptoms can be mild and include itchy eyes, urticaria, or cough. However, the symptoms can progress rapidly to shortness of breath, stridor, angioedema, and shock. Treatment should be initiated immediately and includes epinephrine, steroids, antihistamines, and bronchodilators (if bronchospasm is present). All available data suggest that failure or delay in the administration of epinephrine increases the chance for death from anaphylaxis. The risk for anaphylaxis with any event is dependent on the severity of the patient’s previous reaction, and it seems to be proportional to the rate of symptom onset. Once the symptoms have been controlled, patients should be observed for at

**Fig. 140.1 Massive Hymenoptera envenomation.** (Courtesy Richard Clark, MD.)
Symptoms of allergy and anaphylaxis may be variable and include perioral or pharyngeal tingling, shortness of breath, tachypnea, bronchospasm and wheezing, stridor, chest pain, sudden tachycardia, hypotension, angioedema, and urticaria. Bees and wasps are the most common sources of insect allergic reactions. Because animal-derived antibody products can also result in allergic reactions or anaphylaxis, each patient receiving antivenom must be monitored carefully. The antivenom infusion must be stopped immediately if allergic symptoms such as those listed develop.

Skin testing is a very imperfect (not sensitive, not specific) predictor of subsequent allergic reactions to antivenom. Pretreatment includes antihistamines (e.g., diphenhydramine, 25 to 50 mg intravenously [IV], plus ranitidine, 50 mg IV) and antipyretics (acetaminophen, 500 mg or 15 mg/kg orally [PO]). Treatment of any significant allergic reaction is prompt administration of epinephrine.

- The dose is 0.1 to 0.5 mg IV of a 1:10,000 concentration (0.1 mg/mL); repeat every 5 minutes as needed to titrate for symptoms.

At least 2 hours to ensure resolution of the symptoms. Patients with persistent cardiopulmonary symptoms should be admitted to the hospital. An outline of anaphylaxis treatment is found in Box 140.1 and Table 140.2.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients treated for anaphylaxis should be educated on avoidance of the allergen and use of an epinephrine autoinjector. Wearing a medical bracelet is also advisable. Finally, patients should be referred to an allergist for sensitivity testing and possible venom immunotherapy.

WIDOW SPIDERS (LATRODECTUS SPECIES)

With its distinct shiny black color, bulbous abdominal segment, and ventral orange-red markings, Latrodectus species are some of the most identifiable of all spiders. Latrodectus mactans (black widow) is perhaps the best known of the genus and possesses an hourglass-shaped ventral marking (Fig. 140.2). As is the case with many arthropods, females are the larger of the two sexes, and males do not have fangs capable of piercing human skin. Latrodectus venom contains a potent neurotoxin, α-latrotoxin, a well-characterized protein that induces massive release of neurotransmitters from presynaptic neurons. The resultant effect of these neurotransmitters is activation of the autonomic and somatic nervous systems.

PRESENTING SIGNS AND SYMPTOMS

The bite itself is typically painful, and this discomfort can spread throughout the affected extremity. Local erythema and diaphoresis occur early at the site with a resultant macule developing into a target lesion. The development of painful cramping in large muscle groups and autonomic instability is known as latrotoxicosis. This systemic syndrome has been described as being so severe as to mimic an acute abdomen, even when the site of envenomation is remote from the center mass; the exact pathophysiology of this phenomenon is not well understood. Hypertension, tachycardia, headache, nausea,

priapism, and dyspnea have also been described in association with Latrodectus bites.9

TREATMENT

The mainstays of therapy for widow spider envenomation are adequate analgesia and muscle relaxants. The majority of patients respond to one or multiple doses of opioid analgesics and benzodiazepines, and these medications should be titrated according to patient symptoms.

IgG antivenom for Latrodectus envenomation is available in the United States, but this treatment is often reserved for the rare patients whose pain and muscle spasms are refractory to large doses of analgesics and relaxants. This antivenom is a whole-antibody horse-derived IgG preparation, and anaphylactoid reactions and serum sickness are potential consequences of its administration. Therefore, it should be administered slowly and with caution.10

One vial of antivenom is usually sufficient to relieve symptoms. This preparation should be infused slowly (over a 15- to 30-minute period). Premedication with antihistamines can be considered. The EP must be prepared to administer epinephrine if a severe allergic reaction to horse serum occurs. Additionally, patients must be informed that serum sickness (diffuse papular rash, glomerulonephritis, arthralgias) may occur 10 to 21 days following therapy, although this reaction will rarely be seen with administration of only one vial. Latrodectus antivenom is in very short supply and is not readily available in many facilities. A potentially safer, Fab fragment antivenom is currently being investigated and may be available for use in the United States in the near future.

SPIDERS CAUSING DERMONECROTIC ARACHNIDISM

Loxosceles, or recluse, spiders cause the syndrome of dermonecrotic arachnidism. These spiders, as their
name suggests, prefer dark and isolated spaces such as attics, basements, and closets. They bite only when threatened or disturbed. In contrast to *Latrodectus*, *Loxosceles reclusa* is more difficult to identify. Many possess a violin-shaped dorsal marking (hence in some regions they are called “fiddleback” spiders), but this is not a diagnostic feature of all *L. reclusa*. The only unifying feature of all *Latrodectus* spiders is that they possess only three pairs of eyes, as opposed to the four pairs found in most spiders. Hobo spiders in the Pacific Northwest and several other species are also theorized to cause necrotic complications following bites, but these associations are more controversial. The venom of recluse spiders is a complex mixture of hyaluronidase, ribonucleases, lipases, and sphingomyelinase D, the latter being thought to be responsible for the necrosis.11,12

**PRESENTING SIGNS AND SYMPTOMS**

The most common clinical effect of true recluse spider bites is a progressively necrotic eschar. The lesion evolves from a nonspecific erythematous wheal into an eschar with surrounding rings of blanching and erythema (“red, white, and blue” sign) over a period of days to weeks. The slow destruction of skin structure occurs as a result of the effects of venom on the dermal microcirculation, and it can extend into adjacent tissues in a gravity-dependent manner. These lesions can be cosmetically disfiguring and stressful for patients because they expand and worsen over a period of many days to weeks. It is important to stress to patients that lesions from recluse spiders sometimes progress despite medical treatment.11,12 It is also important to appreciate the rarity of these injuries in comparison with the frequency with which they are reportedly perpetrated; many cutaneous infections are mistaken for recluse bites. In one study, spider bites were confirmed in only 3.8% of all individuals with the chief complaint of a spider bite.13 Rare cases of severe hematologic toxicity with hemolytic anemia, thrombocytopenia, and coagulopathy have been described in association with *Loxosceles* bites, particularly in Brazil.14,15

**TREATMENT**

Therapies aimed at limiting or preventing the necrotic sequelae of recluse spider bites are controversial. The safest management regimen that can be recommended without reservation is gentle cleansing, tetanus prophylaxis, analgesia, antipruritic medications, and immobilization if needed. Disproved treatments include early wound excision, corticosteroids, cyproheptadine, and electric shocks delivered to the bite site to denature the venom components. Hyperbaric oxygen, dapsone, and colchicine have been tried as experimental therapies, but studies proving benefit are thus far lacking. Severely disfiguring or nonhealing bites may require delayed reconstructive procedures once the destructive effect of the venom has halted.

A *Loxosceles* antivenom has been developed for use in Brazil, but based on animal models, it must be given within 24 hours to be effective. Because most patients are seen 2 to 3 days after being bitten, this type of antivenom is not typically a useful adjunct in the treatment of *Loxosceles* spider bites.15 Symptomatic and intensive supportive care is warranted in the rare case of disseminated intravascular coagulation, hemolytic anemia, renal failure, or acute respiratory distress syndrome following the bite of a recluse spider.

**TARANTULAS**

Tarantulas are distributed worldwide and recognizable by their large size and prominent hairlike projections. Large or aggressive species can bite; the effects can range from relatively painless to deep throbbing pain with a febrile reaction that requires analgesics and antipyretics. By rubbing their hind legs against their abdominal wall, tarantulas can “flick” their hairs in the direction of perceived threats, and both dermal and ocular injuries have occurred from the highly irritating “urticating” hairs of tarantulas. The presence of urticaria, hives, intense pruritus, and mild erythema characterizes dermal lesions; ocular exposure to the urticating hairs has resulted in corneal abrasions, iritis, uveitis, and chronic granulomatous reactions (ophthalmia nodosum).16

**TREATMENT**

Therapy is essentially supportive and consists of analgesics and antihistamines. Ophthalmic antibiotics or steroids in conjunction with close follow-up or emergency ophthalmology consultation may be necessary in cases of ocular exposure to tarantula hairs.

**SCORPIONS**

Scorpions are easily recognized by the taillike abdominal segment that forms into a venom-filled bulb with a stinger (telson). In the United States, scorpions are commonly encountered hazards in the Southwest, where *Centruroides exilicauda* (formerly *Centruroides sculpturatus*), or the bark scorpion, is endemic. They commonly hide in dark spaces such as closets and shoes; the exoskeleton’s ability to fluoresce under ultraviolet light is sometimes helpful in locating these creatures. Worldwide, species that represent significant hazards to human health include *Tityus* species in Trinidad and Brazil and *Buthus* and *Parabuthus* species in India, Africa, and the Middle East. Most scorpion stings occur when the creature feels threatened or alarmed.17,18

The venom of *C. exilicauda* is complex and targets excitable membranes. The result is abnormally prolonged opening of sodium channels at the neuromuscular junction and at both sympathetic and parasympathetic nerve endings. Dangerous varieties of scorpions from other countries can cause massive release of catecholamines from nerve terminals, particularly norepinephrine and acetylcholine, which can lead to diverse autonomic effects.

**PRESENTING SIGNS AND SYMPTOMS**

Local effects of erythema and tingling may be present, but these findings may be quite subtle initially. Tapping the site...
of discomfort gently accentuates the reported symptoms, even in the absence of visible skin lesions. Systemic findings are often more dramatic than the local effects and peak around 5 hours after the sting; signs and symptoms commonly include hypertension, tachycardia, convulsions, cranial neuropathies, roving ophthalmpoplegia (also known as oculogyric crisis), ataxia, abdominal cramps, and respiratory failure from neuromuscular dysfunction.17,18

The stings of other scorpion genera may produce unique syndromes. Tityus scorpions in Trinidad and South America can cause pancreatitis, and in India and Africa the Buthus and Parabissessatus varieties can cause pulmonary hemorrhage, gastrointestinal bleeding, and disseminated intravascular coagulation, presumably because of the presence of phospholipase in the venom.

**DIAGNOSTIC TESTING**

Testing of serum electrolytes, CPK, and cardiac isozymes, as well as chest radiography and electrocardiography, should be considered in patients at high risk for cardiac ischemia. Neurologic testing such as computed tomography of the head and lumbar puncture may be required in patients in whom other neurologic disease processes are suspected.

**TREATMENT**

The majority of patients respond to supportive care and aggressive pain management with analgesics and muscle relaxants. Continuous infusion of benzodiazepines may be considered in well-monitored patients to decrease agitation and abnormal motor activity.17 Short-acting antihypertensives such as esmolol or nitroprusside are also appropriate in the setting of severe hypertension and tachycardia.

Respiratory failure or fatigue warrant aggressive airway management and possibly intubation; this complication is especially concerning in the pediatric and elderly populations, which are most vulnerable to mortality from scorpion stings. Rarely, pancreatitis and coagulopathy require intensive supportive care with meticulous fluid management and transfusion of blood products.

Scorpion antivenom directed against different species has been produced for research or clinical use in more than 10 countries, and recommendations for their use are variable. In the United States, a recent study demonstrated improved outcome in critically ill children after treatment with C. exilicauda antivenom.18

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with severe signs and symptoms require admission to the hospital, and intensive care may be necessary for pediatric and elderly patients. Patients who are comfortable and have normal vital signs and results of diagnostic testing can safely be discharged. Wounds from scorpion stings do not usually require specific therapy for infection.

**TICKS (IXODES, DERMACEMENTOR, OTHERS) AND TICK PARALYSIS**

The overwhelming concern regarding ticks is their role as vectors for viral, bacterial, and protozoal infectious diseases. Ticks are arachnid bloodsucking parasites that painlessly attach to their host. In addition, several members of the Dermacentor, Ixodes, and Amblyomma genera of ticks can induce a rapidly progressive syndrome of ascending weakness and loss of deep tendon reflexes called tick paralysis. The condition is most common in the Rocky Mountain states and Pacific Northwestern region of the United States, but the true incidence is unknown because it is not a reportable entity. Girls seem to be affected more often because the pediatric population is more apt to harbor the tick for a longer period before being brought to medical attention and longer hair camouflage the offending tick.

Though not fully characterized, the neurotoxin is presumed to inhibit release of acetylcholine at the neuromuscular junction.

**PRESENTING SIGNS AND SYMPTOMS**

The onset of lower extremity weakness is insidious, similar to Guillain-Barré syndrome, and reflexes tend to be diminished in both. Careful physical examination is the key to diagnosis because the paralytic neurotoxin is secreted by the tick as long as it remains attached to the skin. Although the tick can be found attached to the skin in any anatomic location, well-protected areas such as the clothing waistline and the occipital scalp in victims with long hair are common sites of injury. Respiratory failure is the most feared complication of a delayed diagnosis. In contrast to Guillain-Barré syndrome, the results of cerebrospinal fluid analysis are normal in patients with tick paralysis.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis for ascending paralysis is short and includes Guillain-Barré syndrome, cerebellar ataxia, spinal cord compression, hypokalemic periodic paralysis, and transverse myelitis. Work-up includes basic laboratory studies, lumbar puncture, and central nervous system imaging, all of which would be expected to show normal results in patients with tick paralysis.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Removal of the offending tick rapidly leads to resolution of the symptoms and decreases the likelihood of tick-borne disease transmission. It can be achieved by grasping the tick near the skin with fine-point tweezers and pulling straight outward with steady, gentle traction. All patients with ascending paralysis should be admitted to the hospital, regardless of the cause. Once the tick has been removed and the neurologic symptoms are clearly improving, the patient can be safely discharged.20,21
Caterpillars are the wormlike immature forms of butterflies and moths. Of the 165,000 total species, only 12 families worldwide account for human injuries. In 2009, 1422 exposures were reported to poison centers in the United States. Most of these exposures occur in individuals younger than 18 years. The numerous hairlike projections of these organisms are called setae and, in some species, are actually hollow connections to venom glands capable of piercing the skin and result in envenomation on contact. These solid setae are highly irritating to the skin on contact and are light enough to be dispersed by the wind. In fact, dry weather and strong winds facilitated the dispersion of setae and resulted in an epidemic of dermatitis among Shanghai residents in 1972.

Several illness syndromes caused by caterpillars or butterflies (order Lepidoptera) are recognized. The most common injuries are dermal lesions, sometimes referred to as erucism or cutaneous lepidopterism. In the United States, the most common form of lepidopterism is dermatitis caused by the puss caterpillar, also known as the woolly slug. This flat, fuzzy caterpillar is found in the southern United States from Maryland to Texas. The related flannel moth caterpillar is endemic to New England and the eastern U.S. seaboard. Other species that cause dermatitis include the Automeris io, Megalopyge opercularis, and saddleback caterpillars. All these species induce a stinging, itchy, or painful lesion on contact with the setae. Characteristic lesions are often teardrop shaped in a gridlike pattern and mimic the shape of the offending caterpillar. The woolly slug induces a dull aching pain at the site of parallel papular eruptions. Caterpillar setae can occasionally irritate the eyes or respiratory passages on direct exposure to these surfaces. Distinguishing features and treatment of these lesions are summarized in Table 140.2.

Mites, fleas, lice, and bedbugs are small arthropods that reside in a wide variety of environments. Various mites thrive naturally in or on grains, pets, rodent pests, feathers, furniture, house floors, and straw. Fleas and lice are ectoparasites that feed on the skin surface, whereas the scabies mite is an arachnid endoparasite that burrows under the skin. Fleas and lice are probably more important from an infectious standpoint because of the zoonotic diseases that they can transmit, such as plague and typhus, respectively (Box 140.2). Bedbugs, in particular, have gained much publicity in recent years because of their increasing prevalence. Adults are oval shaped and resemble small (less than 5 mm) cockroaches. Bites from all four can produce self-limited pruritic papules at the feeding site, but scabies is more apt to cause a persistent dermatitis secondary to shedding and leaving fecal droppings embedded in the burrowed skin.

The worldwide prevalence of scabies has been estimated to be approximately 300 million cases annually. Most mites are transmitted via intimate interpersonal contact, but adult forms of the mite can survive remote from human tissue for 24 to 36 hours in bedding, clothing, and furniture. Dogs and cats can host other variants of the scabies mite that cannot complete their life cycle in humans but are able to survive up to more severe complications such as rhabdomyolysis and renal failure.

In contrast to centipedes, millipedes are vegetarians but can induce dermal irritation injuries because they express a toxic substance onto the exoskeleton when threatened. This oily residue can cause ocular irritation and discoloration of the skin that can last for months. Distinguishing features and treatment of these bites are summarized in Table 140.2.
96 hours in human skin. Contact with infected pets can cause self-limited illness, papules, and urticaria in humans.

Severe pruritus and erythematous papules are the most characteristic symptoms of all these bites. Distinguishing flea, lice, and mite bites from one another is very difficult without the offending arthropod present for microscopic examination. All clothing and linen must be laundered in hot water, and potential contacts (prolonged skin-to-skin contact) must be treated simultaneously to avoid reinfection. Scabies-affected pets should also be treated with a scabicide. Features and treatment of these bites are summarized in Table 140.2.

Non-Snake Reptile Bites

Stephen C. Hartsell and Troy E. Madsen

Epidemiology

Crocodilians account for more human injuries and fatalities worldwide than any other non-snake reptile. Three of the largest species are known for unprovoked attacks on humans: the American alligator (*Alligator mississippiensis*), the saltwater crocodile (*Crocodylus porosus*), and the Nile crocodile (*Crocodylus niloticus*). From 1928 through 2008, 567 reports of adverse encounters with American alligators resulted in 24 deaths in the United States. Most injuries were due to a single bite. In Australia, 80% of unprovoked attacks by the saltwater crocodile involved people who were either swimming or wading in water. The Nile crocodile of Africa, though smaller and less territorial, probably accounts for more human fatalities than all other 23 species of crocodilians combined.

Most Gila monster bites are nonaccidental and occur as a result of handling the reptile. Accidental bites have become exceedingly rare. No deaths from Gila monster bites have been reported in the United States in the past 50 years. The Komodo dragon is now known to have a venom apparatus similar to that of the Gila monster, and deaths have been reported as a result of their bites.

Crocodilians

Pathophysiology

Crocodilians survived the Ice Age and are the dominant predators in many of the world’s tropical waterways. The American alligator may be found in the southeastern United States, from North Carolina to Louisiana. The saltwater crocodile is found in Southeast Asia and Australia, with males reaching lengths of up to 23 feet (7 m). Victims of crocodilian attacks sustain trauma from a combination of penetrating, blunt, and sheer force. The saltwater crocodile can generate 2000 psi when it bites. The sheer magnitude of the jaw muscle force sustained with extensive penetrating injuries devitalizes large areas of tissue, thereby making such injuries slow to heal and susceptible to infection. Bites must be considered to be heavily contaminated with multiple bacteria, including *Aeromonas hydrophila*, *Pseudomonas*, and *Proteus* (Fig. 141.1).

Presenting Signs and Symptoms

Crocodilian bites are characterized by punctures and tears. Their teeth are conical and not designed for chewing but for grasping their prey. Among survivors, the extremities were the most commonly injured site, with less than 10% sustaining torso trauma. Crocodilians may also roll their entire body (known as the “death roll”) to disorient and drown the victim, as well as to tear pieces from the victim’s body. The force of the massive jaws may lead to extensive internal injury, but even when bite wounds are not present, the force of the animal’s movement—or even blunt trauma from its tail—may also inflict significant internal trauma. Initial survivors of severe attacks may exhibit hypotension from massive hemorrhage, in addition to respiratory distress from submersion injury.

Differential Diagnosis and Medical Decision Making

Victims of crocodilian bites often have injuries comparable with those sustained in a severe motor vehicle collision. Prehospital care should start with movement of the patient to a safe environment well away from water’s edge. The provider should make sure that airway control, breathing, and circulatory support are adequate with use of the advanced trauma life support (ATLS) protocols. External hemorrhage should be controlled with direct pressure or packing, and chest wounds should be dressed to prevent the development of tension physiology. Extremity fractures should be splinted and suspected major pelvic deformities bound or sheeted. Resuscitation in the hospital should continue according to ATLS protocols, including a focused assessment with sonography for trauma.

A secondary evaluation should be done to determine the extent of tendon, neurologic, and vascular injuries and possible internal organ damage. Underlying fractures and dislocations should be considered, particularly in light of the force and sheering mechanism of the animal’s bite. Depending on
the nature and location of the bite, radiographs can aid in evaluation for bony injury. Computed tomography may be useful to evaluate for internal injury.

PRIORITY ACTIONS

Reptile Bite Wounds
Treat all victims of crocodilian bites as major trauma patients with the potential for massive internal injuries. Extremity bites should be evaluated for underlying vascular, tendon, nerve, or bone injury. Copiously irrigate and débride all wounds, especially crocodilian and Komodo dragon bites. Facial wounds and others with significant cosmetic concern should be closed if the patient is seen early after the bite and does not show signs of infection. Ensure tetanus prophylaxis. Consider a 5-day course of prophylactic antibiotics with close outpatient follow-up to monitor for signs of infection.

TREATMENT

Specialists should be consulted to evaluate and treat internal injuries, nerve and tendon damage, fractures, and major lacerations. Local wound care techniques are mandated to cleanse what are typically very contaminated wounds. Because of the high incidence of infection, all significant wounds need exploration, preferably in the operating room, where débridement of devitalized tissue and thorough decontamination can be accomplished. Prophylactic broad-spectrum antibiotic therapy may be necessary to prevent wound infection. The patient’s tetanus status should be checked and brought up to date.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Disposition is based on the extent of the injuries, but admission should be considered for all patients except those with minor cutaneous extremity trauma. If the patient is discharged, close follow-up is advisable for wound care and to evaluate for wound infection. Prolonged rehabilitation is frequently needed because of the extent of injuries. The public should be advised to contact local wildlife managers about crocodilian activity before recreating in crocodilian-inhabited environments. Care should be taken when swimming, wading in, or approaching water. If attacked, the best defense appears to be to “fight back” by gouging the crocodile’s eyes with thumbs and fingers. If a hand or arm is within the reptile’s mouth, reaching caudally may displace the palatal valve, causing the crocodile to aspirate water and open its mouth.

GILA MONSTER AND BEADED LIZARD

PATHOPHYSIOLOGY

The Gila monster (*Heloderma suspectum*) and the closely related beaded lizard (*Heloderma horridum*) are native to the southwestern United States and Mexico but may be found throughout the world in zoos and as illegal pets. They are characterized by black beadlike scales mixed with bandlike patterns of yellow, white, or pink scales (Fig. 141.2). These reptiles typically range in length from 9 to 32 inches (22 to 81 cm); the beaded lizard is the larger of the two species. Unlike pit vipers, which inject their venom through fangs, *Heloderma* species have a very rudimentary venom delivery mechanism. The animal has individual vertical grooves in its lancet-shaped teeth to deliver venom by capillary-type action from anterior mandibular venom glands. The lizards tend to stay attached to their victims by using mastication to augment the delivery of venom.5,6 Their venom is similar in some respects to rattlesnake venom and can stimulate the release of vasoactive kinin, which leads to hypotension.5

PRESENTING SIGNS AND SYMPTOMS

Patients may arrive at the emergency department (ED) with the lizard still attached. Bite wounds are classically indurated
and erythematous. Significant edema may develop at the site of the wound. Patients often describe excruciating pain associated with the bites. In envenomated patients, weakness, hypotension, and tachycardia are commonly seen as a result of systemic effects of the reptile’s venom.4,5

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

In addition to local pain and swelling, laboratory evaluation assists in determining the severity of envenomation. The most common reported laboratory abnormality in Gila monster bite envenomations is leukocytosis, although coagulopathy has also been reported. Minimum laboratory work-up should include a complete blood count with platelets, basic metabolic panel, and coagulation panel. An electrocardiogram and cardiac enzymes should be considered, especially in symptomatic patients with cardiac risk factors.

Radiographs may be obtained to rule out associated fractures. However, retained teeth do not show up radiographically, and local wound exploration should be performed to rule out this possibility.

**PRIORITY ACTIONS**

**Envenomation by a Gila Monster or Beaded Lizard**

- Observe all patients for 8 hours to watch for the development of signs of envenomation.
- Initiate fluid therapy for hypotension and tachycardia.
- Initiate vasopressor therapy for hypotension and tachycardia unresponsive to fluids.
- Use adequate opiate analgesia to control pain.
- Admit patients with systemic symptoms to the hospital for observation and resolution of symptoms.
- Ensure tetanus prophylaxis if needed.

**TREATMENT**

If still attached, the lizard must be removed from the patient. Increased time of mastication can increase the severity of envenomation. A flame placed under the animal’s jaw will usually result in release within 3 to 5 seconds and decreases the possibility of leaving teeth in the wound. Other techniques, such as immersion in cold water, may also be used. Special care should always be taken to prevent reattachment of the animal to the victim or subsequent attachment to the person removing the reptile.

Envenomation may cause hypotension, tachycardia, and generalized weakness. These symptoms generally respond well to intravenous crystalloid administration. Refractory hypotension may require treatment with vasopressors such as dopamine. No antivenom is commercially available for Gila monster or beaded lizard envenomation.4,6

The most important aspect of evaluation of the wound is physical examination for evidence of vascular or tendon injury and local wound exploration for retained teeth from the animal. The pain typically requires large amounts of opiate analgesics; the few patients who have experienced both rattlesnake and Gila monster bites report much greater pain associated with a Gila monster bite. The pain generally peaks between 15 and 45 minutes following the bite and may last for days.4,7

Although the use of prophylactic antibiotics for animal bites remains somewhat controversial, patients may benefit from treatment with broad-spectrum antibiotics, such as amoxicillin-clavulanate (Augmentin) for 3 to 5 days, with specific instructions to watch for signs of infection. Delayed or loose wound closure should be considered to prevent early infection, and the patient should be instructed about local wound care techniques.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

All symptomatic and potentially envenomated patients should be admitted for monitoring, supportive care, and pain management. Patients who remain asymptomatic and have normal laboratory values may be discharged after a period of 8 hours of observation. Tetanus prophylaxis is necessary if the patient’s immunization status is not up to date. All patients should be reevaluated in 24 to 48 hours for evidence of the development of infection.

**KOMODO DRAGON**

**PATHOPHYSIOLOGY**

Native to the islands of Indonesia, the Komodo dragon (Varanus komodoensis) is the largest lizard in the world; it can reach lengths greater than 10 feet (3 m) and weigh as much as 300 lb (136 kg) (Fig. 141.3). These lizards can move as fast as 13 mph (20 km/hr) over short distances and take down prey as large as water buffalo. Komodo dragons’ teeth are sharklike, with posterior serrations that create deep open wounds to facilitate envenomation. Its venom is known to cause coagulopathy, increased vascular permeability, and vasodilatation.8 Victims bleed profusely from large wounds. Hypotension and shock develop rapidly and lead to death. If the initial attack does not kill the victim, infections from multiple pathogenic bacteria in the Komodo’s saliva can lead to sepsis and death.9
be controlled with direct pressure or packing, and chest wounds should be dressed to prevent the development of tension physi-
ology. Extremity fractures should be splinted. Resuscitation in the hospital should continue according to ATLS protocols, with immediate attention to large open wounds, control of hemorrhage, and potential coagulopathy. Because of possible significant blood loss, blood products, including packed red blood cells, platelets, and coagulation factors, should be started early. With the additional vasodilation from envenomation, vasopres-
sors may be needed for refractory hypotension. A broad-
spectrum intravenous antibiotic should also be started immediately. No antivenom is commercially available for treat-
ment of komodo dragon enveromation.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Survivors of significant Komodo dragon attacks should be admitted to an intensive care unit. Victims of domestic attacks have required admission and speciality care as a result of underlying tendon and neurovascular injury from extremity wounds. As with all bite wounds, delayed closure of the wound may be required.

Outpatient treatment of simple lacerations or puncture wounds includes tetanus prophylaxis, broad-spectrum antibiotics, and close follow-up to monitor for signs of wound infection. Hospitalization for intravenous antibiotics should be considered because of the high risk for significant infection in these wounds.

GREEN IGUANA

PATHOPHYSIOLOGY

The green iguana (Iguana iguana) is native to Central and South America. It is the most common lizard sold as a pet in the United States (Fig. 141.4). Feral iguana populations can now be found in Florida, Hawaii, and southern Texas. Iguanas are usually docile but can cause injuries with their teeth, claws, and tail. They can also be a source of Salmonella infec-
tion.10 No specific venom is associated with iguana bites.
**PRESENTING SIGNS AND SYMPTOMS**

Most trauma from iguana bites is superficial soft tissue injury, although tendon injuries have been reported. The majority of bites (80%) occur on the upper extremities, particularly the fingers, with 19% occurring on the face. As with any bite, patients may have infectious complications, particularly those with delayed care or immunosuppression.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Extensive diagnostic testing is not generally necessary in cases of iguana bites. Blood and local wound cultures may be useful for patients with established wound infections and systemic signs and symptoms. During physical examination the physician should look for underlying tendon and neurovascular injury. Associated bone damage is rare with iguana bites.

**TREATMENT**

As with any animal bite wounds, delayed closure should be considered and any underlying neurovascular or tendon injuries treated as appropriate. Prophylactic antibiotics remain somewhat controversial, but a 3- to 5-day course of ciprofloxacin should be considered in light of the Salmonella typically carried by the green iguana. In patients with wound infections, treatment with intravenous ceftriaxone may be beneficial. Tetanus prophylaxis is important.

**SNAPPING TURTLE**

Both the common and the alligator snapping turtles have powerful beaklike jaws without teeth but with sharp occlusal surfaces adapted for cutting and holding prey. They are not aggressive but curious about activity occurring around them.

**PATHOPHYSIOLOGY**

Snapping turtles will bite out of self-defense when cornered or cut off from their aquatic environment. Most bites tend to occur when victims put their fingers near the turtle’s head. These turtles may be as long as 20 inches (50 cm) and have a long neck that may extend up to two thirds the length of their body. These freshwater turtles live in habitats ranging from southeastern Canada to Mexico and Ecuador.

**PRESENTING SIGNS AND SYMPTOMS**

A snapping turtle’s bite typically causes only soft tissue injury; however, the force of its bite may lead to digit amputation, fractures, or damage to underlying neurovascular structures. Patients with delayed arrival at the ED may show signs of infection.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

When performing the physical examination, the physician should be aware of the potential for damage to nerve, tendon, vascular, and bony structures because of the force of a snapping turtle’s bite. Edema may be present and bleeding should be controlled with local wound pressure. Plain radiography may be helpful to evaluate for injury to bones.

**TREATMENT**

Attempts to remove a turtle still attached to a patient will cause it to exert greater bite pressure and result in further injury. Although they rarely remain attached, they will typically release their bite if placed in water. The bite wound should be thoroughly irrigated and débrided. Management of tendon, neurovascular, and bony trauma may require specialty consultation. Delayed closure of wounds may be necessary. Because snapping turtles may carry Salmonella, antibiotic prophylaxis with ciprofloxacin is advisable; in patients with significant wound infections, treatment with intravenous ceftriaxone is recommended.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

All patients should be educated on the signs of infection and the need for elevation of any injured extremity. Reevaluation of the patient should be scheduled for 24 to 48 hours after discharge.

Marine Food-Borne Poisoning, Envenomation, and Traumatic Injuries

Stephen Thornton and Richard F. Clark

**KEY POINTS**

- Scombroid is thought to be caused by breakdown of histidine into histamine in dark-meat marine fish and can be managed with antihistamines.
- Ciguatera poisoning results from the consumption of large tropical predatory reef fish that have bioaccumulated ciguatoxin; it causes gastrointestinal distress and neurologic symptoms.
- Tetrodotoxin blocks sodium channels and can lead to ascending paralysis and respiratory failure.
- Box jellyfish (Cubozoa), Portuguese man-of-war (Hydrozoa), and other stinging marine invertebrates envenomate humans via nematocysts that contain a stinging barb and venom.
- The box jellyfish (Chironex fleckeri) and related species cause the most morbidity and mortality of all marine envenomations.
- Acetic acid immersion is recommended for the treatment of box jellyfish envenomation but may worsen man-o-war envenomation.
- Hot water immersion appears to be an effective treatment of almost all marine envenomations.
- Sea snake venom is neurotoxic and myotoxic. Treatment with antivenom is effective.
- Evaluation for a retained foreign body should be considered with stingray and spiny fish envenomation.
- Wound infection is a common complication of spiny fish and stingray envenomation, and prophylactic antibiotics effective against common pathogens such as *Vibrio* species should be considered.
- Direct marine injuries are usually abrasions and contusions, but fatal attacks by sharks and large predatory fish do occur.

**PERSPECTIVE**

As human contact with the ocean and the organisms that live in it continues to increase, the impact of poisonings, envenomations, and direct trauma by these marine organisms will also grow. Marine food-borne poisonings can cause large outbreaks, and direct envenomation by the innumerable stinging organisms in the ocean cause significant morbidity. Less common but more dramatic, attacks by sharks and other large marine organisms cause deaths every year. Thus, it is important for physicians to be aware of the hazards posed by marine organisms and be familiar with appropriate treatment options.

**EPIDEMIOLOGY**

Poisoning from the ingestion of marine animals such as shellfish and fish constitutes a small but consistent source of food poisoning outbreaks and illnesses. Although mortality is low, morbidity can be significant, with many patients needing to seek medical care. Tetrodotoxin poisoning is an exception, and significant mortality has been reported.

Even though the vast majority of marine sea life is harmless to humans, a small but important percentage does cause human envenomation with resulting morbidity and mortality. It is difficult to quantify the annual number of marine envenomations because most victims will not seek medical care and reporting cases to health departments or poison centers is not mandatory. Some estimates suggest the number of marine envenomations worldwide to be greater than 10 million per year, with the majority being caused by jellyfish. Deaths are reported every year from envenomation by certain species of jellyfish, most commonly the box jellyfish.

The true number of traumatic injuries caused by marine life is difficult to estimate. Most will consist of only minor abrasions and contusions, but occasional fatal traumatic injuries do occur. Attacks by sharks and large predatory fish cause human fatalities every year. Stingray barbs can cause significant direct trauma and death.

**MARINE FOOD-BORNE POISONINGS**

**PATHOPHYSIOLOGY**

The toxins responsible for the signs and symptoms of marine food-borne illnesses are primarily produced in microorganisms such as dinoflagellates, diatoms, and marine bacteria and are bioaccumulated by shellfish or fish, which are then ingested by humans and result in toxicity. Most of these toxins modulate neuronal and muscle sodium channels. Scombroid is not caused by a preformed toxin but rather by breakdown...
of histidine into histamine in inadequately stored dark-meat fish. Table 142.1 lists the common marine food-borne poisonings, causative toxins, and typical sources of such poisonings.8

### PRESENTING SIGNS AND SYMPTOMS

Table 142.1 lists the typical onset and common symptoms associated with marine food-borne poisonings. Typically, a history of seafood ingestion can be obtained. In most cases the symptoms are manifested within minutes to hours and include a mixture of gastroenteritis (nausea, vomiting, and diarrhea) and often dramatic neurologic findings.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The differential diagnosis for marine food-borne poisoning includes disease processes that cause acute neurologic symptoms with or without gastrointestinal symptoms. Botulism, myasthenia gravis, poliomyelitis, and tick paralysis should be considered. In cases in which the neurologic symptoms are not as obvious, the more common bacterial causes of food-borne poisoning would also need to be considered. The diagnosis of marine food-borne poisoning must be made on a clinical basis because testing for the specific toxins is not readily available.

### TREATMENT

Treatment of marine food-borne poisoning is entirely supportive (see Table 142.1). Attention should be paid to fluid resuscitation and control of nausea and vomiting with antiemetics (ondansetron, 4 to 8 mg intravenously as needed). Although scombroid can be treated with antihistamine therapy, no antidotes are available for any other seafood toxin-mediated poisonings.

### MARINE ENVENOMATION

Envenomation can occur from both marine invertebrates and vertebrates. Members of the Cnidaria phylum, which includes the box jellyfish, true jellyfish, Portuguese man-o-war, and sea...
anemone, have nematocysts with hollow venomous barbs that deliver venom hypodermically. Stingrays have a serrated spine connected to a venom gland located on the tail that can be impaled into unsuspecting victims, whereas the Scorpaenidae family of fish (stonefish, lionfish, scorpion fish) have venomous spines on their fins (Fig. 142.1). Table 142.2 lists the most medically important offending marine organisms and their toxicity.\textsuperscript{5,9,15}

**PRESENTING SIGNS AND SYMPTOMS**

The signs and symptoms of marine envenomation depend on the offending organism. Local pain and irritation are the most common symptoms, especially when nematocysts and spines are involved (Fig. 142.2). However, certain marine organisms can cause severe systemic symptoms and even death. The Australian box jellyfish (*Chironex fleckeri*) can cause sudden cardiopulmonary collapse.\textsuperscript{5} The Irukandji jellyfish (*Carukia barnesi*) can cause Irukandji syndrome, a condition characterized by severe whole-body pain and spasms, tachycardia, and severe hypertension, and it has caused deaths.\textsuperscript{12} The blue-ringed octopus has tetrodotoxin in its venom, which can cause paralysis and respiratory failure.\textsuperscript{13} The cone snail’s venom is a complex mixture of peptides that can lead to rapid paralysis and death.\textsuperscript{14} Stonefish envenomation can result in cardiovascular instability and death, although severe local effects are more common.\textsuperscript{10} Sea snake venom has both a neurotoxic component, which leads to ascending paralysis, and a myotoxic component, which causes muscle breakdown.\textsuperscript{15} Table 142.2 summarizes the signs and symptoms of the more significant marine envenomations.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Frequently, the identity of the offending marine organism will not be known. The geographic location can be a useful predictor, and physicians should be aware of the venomous marine organisms in their local area. It can be helpful to look for physical clues, such as retained jellyfish tentacles and puncture marks. The presence of severe local pain often indicates a Cnidaria or fish envenomation, whereas significant neurologic symptoms, such as weakness, should raise suspicion for cone snail or other neurotoxic organisms.

**TREATMENT**

Treatment of marine envenomation begins with addressing the patient’s airway, breathing, and circulation status. Typically, good supportive care and pain control are all that is needed. Hot water immersion is recommended to control the pain caused by Cnidaria, Scorpaenidae fish, and stingray envenomation and is efficacious because of the heat-labile properties of the neurotoxic component of the venom responsible for the pain. This is typically achieved by immersing the affected body part in water heated to approximately 42°C to 45°C for 20 minutes.\textsuperscript{16,17} Acetic acid may have a role in inactivating the nematocysts of the box jellyfish and Irukandji jellyfish but should not be used on other types of jellyfish because it may worsen these envenomations.\textsuperscript{15} Recently, topical lidocaine was shown to help in alleviating the pain and inactivating nematocysts from several different species of Cnidaria, including the Portuguese man-o-war.\textsuperscript{19} Antivenom therapy is available to treat poisoning by the Australian box jellyfish, the stonefish, and the sea snake.\textsuperscript{20} Evaluation for a retained foreign body should also be considered, especially with stingray and sea urchin envenomation\textsuperscript{21,22} (Fig. 142.3). Table 142.2 summarizes the recommended treatments.

**MARINE TRAUMATIC INJURIES**

**PATHOPHYSIOLOGY**

Traumatic marine injuries are most often caused by the simple action of scraping against the rock-hard and sometimes razor-sharp exoskeletons of sponges, corals, and other sessile marine organisms. Bites from sharks and fish cause trauma directly related to the size of the animal, force of the bite, and

GI, Gastrointestinal.
traumatic marine injuries. Control of bleeding and wound irrigation are important. Because infections can complicate these injuries, prophylactic antibiotics should be considered. Injuries to tendons, ligaments, and other vital structures should be evaluated and addressed.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

All the marine food-borne illnesses are self-limited, although amnestic shellfish poisoning has been linked to long-term neurologic sequelae. Patients with suspected tetrodotoxin poisoning should be admitted to the hospital for observation. Most other patients who are asymptomatic after treatment can be discharged. Those with ongoing or severe symptoms should be admitted. The local public health department should be informed of suspected cases of marine food-borne poisoning.

The vast majority of marine envenomations will be self-limited and resolve with simple supportive care. Infection from sea urchin spines, fish spines, and stingray barbs is well documented, and prophylactic treatment with antibiotics effective against pathogens such as *Vibrio* species should be considered. Patients with persistent or severe pain may need to be admitted, as will any patient with envenomation by a potentially neurotoxic organism.

Serious injuries may need treatment by a trauma or orthopedic surgeon, either on an emergency basis or as an outpatient. Otherwise, good wound care measures should be explained to the patient and return precautions focusing on signs and symptoms of infection stressed.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The offending organisms may or may not be known to the victim, and concomitant envenomation should be considered. Radiographic evaluation may be needed. The most important medical decision to be made is whether the injury is severe enough to warrant specialist care by a trauma, vascular, or orthopedic surgeon.

**TREATMENT**

After initially addressing the airway, breathing, and circulation, direct wound care is usually sufficient to treat most cutting nature of the teeth. The severity of direct injuries from stingray barbs depends on the location where the victim was impaled.

General Approach to the Poisoned Patient

Amy E. Zosel

**KEY POINTS**

- The mainstay of treatment of a poisoned patient is good symptomatic and supportive care.
- Observation is one of the most critical aspects in the management of poisoned patients.
- The most common substance categories associated with fatalities are sedative-hypnotics, antipsychotics, cardiovascular medications, opioids, and acetaminophen combination products.
- All substances can be poisonous; toxicity usually depends on the dose and the duration of exposure.
- Toxidromes are symptom complexes that may provide clues to the identity of the offending agent on the basis of specific pharmacologic principles; they represent “physiologic fingerprints.”
- In general, hypotension in the setting of poisoning is best treated with direct-acting pressors.
- In patients with an unknown ingestion, activated charcoal is the most efficacious decontamination method, but its use should be limited to those who are awake and alert and/or have a protected airway (self-protected or intubated).

**EPIDEMIOLOGY**

Toxicology and poisons have always been of great interest to the public. Toxicology is the study of harmful interactions between chemical or physical agents and biologic systems.

It is believed that approximately 5.3 million poisoning exposures take place every year in the United States, but only about half are reported to poison control centers. The American Association of Poison Control Centers reported 2,479,355 cases of poisoning during 2009, with 93.8% occurring at a residence and just 1.5% at the workplace. Children younger than 3 years were involved in 46.0% of reported poisonings. About 82% of the poisonings were unintentional, and suicide attempts accounted for just 8.9% of cases.1

**PRESENTING SIGNS AND SYMPTOMS**

A poisoned patient may have many different clinical symptoms, including cardiac dysrhythmias, altered mental status, seizures, nausea and vomiting, and respiratory depression. In many cases the offending agent is initially unknown. Vital signs, including pulse oximetry values, are important to obtain (Table 143.1) and should be measured often in a poisoned patient. Vital signs (temperature, pulse, respirations, blood pressure, pulse oximetry) are helpful because they can provide clues to the type of poisoning. Physical findings such as pupil size, odor, seizure activity, and dermatologic changes can also provide clues to the offending agent (Tables 143.2 to 143.4). Emergency physicians (EPs) should be sure to examine for diaphoresis under the axilla, which may be the only body part that exhibits this finding. It is essential to note that patients with mixed ingestions may not have the classic initial signs and symptoms.

Patients who have ingested poisons may not appear to be critically ill initially, but they all have the potential for clinical deterioration.

The history obtained from the patient may be unreliable.2 It is crucial for emergency department (ED) personnel to also obtain additional history from family and friends. The paramedics who brought the patient can provide information about the scene where the overdose took place. What behavior did the patient have at the scene or before arrival? Were there seizures, emesis, changing vital signs? Were there any medicine bottles were found and, if so, were any pills were missing from the bottles? The patient’s primary care physician or psychiatrist may provide important information. Frequently, the patient’s pharmacy can be called to obtain lists of current medications and the last fill date. It is crucial to obtain an occupational history and to review past medical records for any poisoned patient. The initial work-up should determine whether a specific patient has been exposed to an agent for which an antidote (or other specific treatment) exists (Box 143.1).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

**TOXIDROMES**

Several drugs and toxins are associated with specific toxidromes (Table 143.5). Toxidromes are symptom complexes that may provide clues to the identity of the offending agent. They are based on specific pharmacologic principles and represent the “physiologic fingerprints” of the associated substances. An anticholinergic toxidrome, for example, is caused by parasympatholytic substances such as antihistamines, jimsonweed, tricyclic antidepressants (TCAs), and phenothiazines. Affected patients may exhibit hypertension, tachycardia,
fever, delirium, and mydriasis. Sympathomimetic toxidromes resemble anticholinergic toxidromes except that parasympatholytic agents produce silent bowel sounds and dry skin.

The following diagnostic studies should be performed in poisoned patients: serum acetaminophen and acetylsalicylic acid measurements, blood ethanol measurement, blood chemistry panel, electrocardiogram (ECG), pulse oximetry, and serum glucose measurement (Box 143.2). Toxicology screening may confirm exposure to a toxicant but does not usually change management (see later discussion). A blood chemistry profile can be extremely useful, especially in determining the anion gap.\(^3,4\) The anion gap is calculated by the formula

\[
\text{Anion Gap} = \left(\text{Na}^+ - [\text{Cl}^- + \text{HCO}_3^-]\right)
\]

The normal range of anion gap varies from 3 to 12 mEq/L. An increase in the anion gap may indicate an intoxication, but EP must be aware that a normal anion gap does not rule out poisoning. Conditions such as hypoalbuminemia can alter the anion gap. Every 1-g/L decrease in plasma albumin leads in a drop in the anion gap of 2.5 mEq/L. Multiple conditions can cause metabolic acidosis with an elevated anion gap, and the mnemonic “A CAT MUD PILES” is an easy way to remember most of them (Box 143.3). It is important to note than any toxin that can cause seizures or other processes leading to lactic acidosis can also cause an anion gap. A decreased anion gap can be seen with bromide and lithium poisonings.

Measurement of serum osmolality may be useful for some toxin ingestions and should be ordered if toxic alcohols are suspected but results of toxic alcohol testing will be delayed (see Chapter 151).

A normal osmolar gap should be less than 10. An elevated osmolar gap suggests intoxication, although a low or no osmolar gap does not exclude intoxication. An elevated osmolar gap is seen early after the ingestion of methanol, ethylene glycol, diuretics (mannitol), ethanol, and isopropyl alcohol.

\[^3\] An increase in the anion gap may indicate an intoxication, but EP must be aware that a normal anion gap does not rule out poisoning.

\[^4\] Conditions such as hypoalbuminemia can alter the anion gap.

\[^5\] Multiple conditions can cause metabolic acidosis with an elevated anion gap, and the mnemonic “A CAT MUD PILES” is an easy way to remember most of them.
alcohol and reflects the presence of the parent compound. Once the parent compound is metabolized to the toxic acid metabolite, in the case of methanol and ethylene glycol, the osmolar gap is low and the anion gap is high.

Patients with possible poisoning should undergo cardiac monitoring. In cases of unknown ingestion or ingestions for which cardiac abnormalities are a known side effect, a 12-lead ECG should be evaluated for QRS and QT intervals, morphology, and rhythm. A wide QRS interval may be seen with the ingestion of any agent that causes sodium channel blockade, such as TCAs and cocaine. A long QT interval may be seen with many ingestions, such as phenothiazine and methadone. Variable atrioventricular block is associated with digoxin overdose, and ischemic changes can be the result of hypoxemia secondary to carbon monoxide poisoning.

TOXICOLOGY SCREENS
Toxicology screens are of variable utility. Urine screens were specifically designed for the drugs of abuse but have high false-positive and false-negative rates (Box 143.4). Qualitative findings (i.e., yes/no tests) do not provide information about the exact time of ingestion or the severity of

### BOX 143.1 Questions to Ask About a Poisoned Patient

**Why?**
Was the poisoning unintentional or intentional?

**Where?**
Did the ingestion occur inside or outside? While the patient was alone, at a party, or at work?

**What?**
What was the environment like?

**What?**
Question emergency medical services personnel and police, as well as family and friends of the patient, to learn what the substance is. What poisons or drugs were available?

**When?**
How long since the ingestion?

**Who?**
When was the person last seen in their general state of health (i.e., normal)?

**Who?**
Who was at the scene and knows what occurred?

### BOX 143.2 Key Points for Ordering Diagnostic Studies in a Poisoned Patient

Treat the patient, not the laboratory results.

Order laboratory tests according to the signs and symptoms.

The test results may not correlate with the toxidromes.

Drug screens lack clinical significance in some cases.

A test may not be rapidly available; check with the laboratory about turnaround times.

It is important to know what the specific laboratory drug panel covers.

### BOX 143.3 Mnemonic for Causes of Elevated Anion Gap Metabolic Acidosis: A CAT MUD PILES

- Alcohol ketoacidosis
- Cyanide, Carbon monoxide
- Alcohol
- Toluene
- Methanol, Metformin, Massive acetaminophen
- Uremia
- Diabetic ketoacidosis
- Paraldehyde
- Iron, Isoniazid
- Lactic acidosis
- Ethylene glycol
- Salicylates, Strychnine

### BOX 143.4 Drug Detection on Routine Urinary Drug Screens

**Drugs Detected**
- Amphetamines, often misses MDMA, many false positives
- Barbiturates
- Benzodiazepines, often does not detect lorazepam or alprazolam
- Cannabinoids
- Cocaine metabolites
- Ethanol
- Opioids, naturally occurring (codeine, morphine, heroin) well detected, synthetics (fentanyl, oxycodone, meperidine, methadone) often not detected
- Phencyclidine (PCP)
- Propoxyphene

MDMA, Methylene dioxy methamphetamine.
impairment (Table 143.6). Serum is useful for determining quantitative levels of a specific drug (Box 143.5). Treatment is best based on the signs and symptoms. When in doubt, talk to your laboratory manager regarding your particular laboratory assay’s false-negative and false-positive rates, as well as which specific substances cross-react to cause a false-positive result. A comprehensive urine toxicology test, though not performed in most laboratories, can be helpful in cases in which the exact substance must be known. An example would be an intoxicated 3-year-old child whose parents deny any exposure.

When drug metabolites circulate in blood, they enter the scalp’s blood vessels and are filtered through the hair. These metabolites remain in hair and may provide a permanent record of drug use when tested. Hair is constantly exposed to the extracorporal environment and can thus test positive for
substances that the patient has not ingested. Saliva testing is limited to detection of very recent drug use, so it will probably be confined to detecting current intoxication only.

If a sample tests positive on initial screening, a second method should be used to confirm the initial result. Positive results from two different methods operating on different chemical principles greatly decrease the possibility that a methodologic problem or a “cross-reacting” substance could have created the positive result. A confirmation assay should usually be carried out with a method that has comparable sensitivity and higher specificity (or selectivity) than a screening assay. Examples of confirmation methods are gas chromatography, gas chromatography with mass spectrometry, and high-performance liquid chromatography (Table 143.7).

Passive inhalation of marijuana smoke cannot lead to a positive urine test result for its metabolites. Inadvertent exposure to marijuana is commonly claimed as the basis for a positive urine drug screen result. Clinical studies have shown that it is unlikely that an individual who does not smoke marijuana could unknowingly inhale enough marijuana smoke

passively for urine to contain a drug concentration detectable at the cutoff used in current urinalysis methods.

RADIOGRAPHIC EVALUATION

Table 143.8 summarizes the radiographic findings associated with toxic ingestions.

TREATMENT

The primary treatment of a poisoned patient is to stabilize the airway, breathing, and circulation. Initial management includes attention to the ABCDs of resuscitation for a toxic ingestion:

Airway
Breathing, oxygen
Circulation
Dextrose, naloxone

After initial stabilization of a critically ill patient, specific antidote therapy is administered if applicable (Table 143.9), a detailed history is elicited, and a physical examination is performed. Patients who are externally contaminated with a toxicant that may injure staff must be decontaminated immediately to avoid incapacitation of health care staff.
and the facility. Patients should undergo skin and eye decontamination, including removal of all clothing and washing of the skin with soap and water if indicated. Care should be taken to protect health care providers from exposure.

Establishing and maintaining an airway with adequate breathing should occur first. Supplemental oxygen should be administered through a nonrebreather mask. Death from intoxication can occur as a result of loss of the airway protective reflexes, and the patient should be intubated if the airway needs to be protected or the patient cannot be oxygenated or ventilated. Because it is hydrolyzed by plasma cholinesterase, succinylcholine can exacerbate cholinergic toxicity. Organophosphates can prolong the effects of succinylcholine. Electrical cardiac pacing may be effective in cases of mild to moderate drug-induced bradycardia. In patients with drug-induced cardiac arrest, electrical cardioversion or defibrillation per advanced cardiac life support guidelines is appropriate for those who are pulseless and have ventricular tachycardia or ventricular fibrillation. In extreme cases, cardiopulmonary bypass may be performed.

Circulation should be maintained and hypotension treated aggressively. Intravascular volume should be restored with crystalloid fluid, and if the hypotension has not resolved after fluid administration, direct-acting pressors, such as epinephrine or norepinephrine, are the preferred agents. In cases of symptomatic calcium channel blocker overdose, the antidote of choice is high-dose insulin-euglycemia therapy. The goal of this therapy is increased blood pressure leading to improved end-organ perfusion. The exact mechanism by which insulin-dextrose therapy improves ionotropy and increased peripheral vascular resistance is not well

*These are typical doses. Dosing may vary according to the patient and clinical picture. Consult with your medical toxicologist and pharmacist when in doubt. Your local poison center may be reached at 1-800-222-1222.

†May cross-react with penicillin in allergic patients.

‡Should not be used if the patient has signs of tricyclic antidepressant toxicity or a history of seizures.

§Has a much longer half-life than naloxone does.
understood. However, insulin seems to stimulate myocardial metabolism and improves glucose update by cardiac myocytes. Regular insulin, given as a 1 to 2 U/kg bolus followed by 0.5 to 2 U/kg while euglycemia is maintained (using 5% to 10% dextrose solution given as a bolus, then a drip), improves myocardial contractility, cardiac output, and blood pressure. Benzodiazepines are first-line agents for toxicant-induced hypertension. Beta-blockers are contraindicated because they may block the \( \beta \) receptors, thereby leaving the \( \alpha \)-adrenergic stimulation unopposed and worsening the hypertension. In patients with a drug-induced hypertensive emergency refractory to benzodiazepines, short-acting antihypertensive agents, such as nitroprusside, should be administered. Labetalol is a third-line agent, effective at times for drug-induced hypertensive emergencies associated with sympathomimetic poisoning.

Treatment of drug-induced acute coronary syndromes is similar to that recommended for drug-induced hypertensive emergencies. Catheterization studies have shown that (1) nitroglycerin and phentolamine (an alpha-blocker) reverse cocaine-induced vasoconstriction, (2) labetalol has no significant effect, and (3) propranolol worsens it. Therefore, benzodiazepines and nitroglycerin are first-line agents, phentolamine is second-line, and propranolol is contraindicated for drug-induced coronary syndromes. 5,6

In cases of poisoning it is important to treat the patient, not the toxin. The EP should deal with the ABCDs of resuscitation, hypotension, seizures, and cardiac dysrhythmias aggressively. Such treatments can be started without knowledge of what the toxin is. Serial vital sign determination and physical examination are crucial. Progressive neurologic deterioration must be detected early and dealt with appropriately. Observation is one of the most critical aspects of the management of poisoned patients.

**"COMA COCKTAIL"**

**Coma cocktail** is a slang term used to describe a combination of agents that have traditionally been given to poisoned patients with altered consciousness. It consists of dextrose, oxygen, naloxone, and thiamine. A mnemonic to remember this cocktail is DON’T forget. Use of a coma cocktail can be both therapeutic and diagnostic.

Hypoglycemia must be considered in all patients with altered mental status or active seizures. An overdosed patient can often be hypoglycemic because of the offending agent. An empiric therapy for coma, administer 50 to 100 mL (25 to 50 g) of 50% dextrose intravenously. Pediatric patients should receive 2 to 4 mL/kg of 25% dextrose IV. Neonates should receive 10% dextrose. Boluses should be given over several minutes and can be repeated, if necessary.

Naloxone reverses the coma and respiratory depression induced by opioids. It can also be used diagnostically. An initial dose of 0.2 to 0.4 mg is administered intravenously, and if no response is seen after 2 to 3 minutes, an additional 1 to 2 mg can be administered; doses can be repeated up to a total of 10 mg as needed. More than 10 mg may be required and may have to be given as an intravenous drip with higher grades of heroin, pentazocine, diphenoxylate, meperidine, propoxyphene, and methadone overdose. Naloxone has a short half-life (20 to 30 minutes), and its effect does not last as long as the effects of most opioids. Therefore, if respiratory depression develops after an initial dose of naloxone, a naloxone drip should be started and the patient admitted to the intensive care unit. The naloxone is mixed with D\(_5\)W and given at a rate that delivers two thirds of the initial reversal dose per hour. 7 Acute pulmonary edema, opioid withdrawal, and seizures have been reported with naloxone administration. 8,9

Thiamine, 100 mg given intravenously or orally, should be reserved for alcoholic, malnourished patients. Despite traditional belief, giving thiamine to every comatose patient to prevent Wernicke-Korsakoff syndrome is not well supported by the literature. No evidence has shown that dextrose should be withheld until thiamine is administered. 10

Flumazenil is a benzodiazepine reversal agent that can be used for a pure acute benzodiazepine overdose or when reversal of therapeutic conscious sedation is desired. It can potentially reverse the seizure-protecting properties of benzodiazepines in mixed drug ingestions (TCAs). 11 Because flumazenil can induce acute withdrawal symptoms in long-term benzodiazepine abusers, it is contraindicated in patients with a history of long-term benzodiazepine use, seizure disorder, and concomitant TCA ingestion. Flumazenil should not be used routinely to arouse an unconscious patient with overdose because it is often unknown whether a patient is a chronic benzodiazepine user. In a large prospective trial of unconscious patients suspected of benzodiazepine overdose, investigators did not observe any significant side effects with flumazenil. 12 However, serious complications of flumazenil have now been reported, including seizures, ventricular arrhythmias, and benzodiazepine withdrawal in patients who are chronic users. 13 If partial reversal of benzodiazepine intoxication is necessary, the smallest possible dose of flumazenil, 0.05 to 0.1 mg, should be diluted in 10 mL of saline or D\(_5\)W and given slowly intravenously, over a period of several minutes. If there is no initial response, 0.3 mg may be given. If there is still no response, 0.5 mg can be given every 30 seconds for a maximum dose of 3 mg. Goals are respiratory sufficiency and verbal responsiveness, not complete arousal.

**DECONTAMINATION**

Methods of decontamination include gastric emptying (administration of syrup of ipecac and gastric lavage), activated charcoal, and whole-bowel irrigation. There is some controversy about the roles of gastric lavage, activated charcoal, and cathartics in decontaminating a poisoned patient, as well as little support in the medical literature for such treatment. After a delay of 60 minutes or more after ingestion, very little of the ingested drug is likely to be removed by gastric lavage. In some circumstances, aggressive decontamination may be lifesaving, even more than 1 to 2 hours after ingestion. Examples are the ingestion of highly toxic drugs as calcium channel blockers, drugs not adsorbed by charcoal, and sustained-release or enteric-coated products.

Use of syrup of ipecac to induce emesis is no longer part of the treatment of any ingestion. Persistent vomiting after the use of ipecac is likely to delay the administration of activated charcoal. No evidence from clinical studies has shown that ipecac improves the outcome of poisoned patients, and its routine administration in the ED should be abandoned. 14 The only useful clinical situation would be a patient with a life-threatening ingestion many hours from medical care, with no other forms of decontamination available.

Gastric lavage is a time-consuming procedure that also poses a risk for aspiration and other injury. The concept is to
try to wash out the stomach contents before absorption. It may still be useful when the toxin has not yet passed the pylorus. Gastric lavage should not be used routinely for the management of poisoned patients, however. In general, there is no advantage to gastric emptying more than 60 minutes after the ingestion. Gastric lavage is performed by inserting a 36- to 40-French tube into the patient’s stomach and “washing out” the stomach with 300-mL aliquots of normal saline until clear. Unless a patient is intubated, gastric lavage is contraindicated if the airway protective reflexes are lost. It is also contraindicated if a hydrocarbon with high aspiration potential or a corrosive substance has been ingested. Gastric lavage should not be considered unless a patient has ingested a potentially life-threatening amount of a poison, no antidote exists, and the procedure can be undertaken within 60 minutes of the ingestion.17 Multiple studies have shown no advantage of gastric emptying over activated charcoal in decreasing absorption.

In a patient with an unknown ingestion, administration of activated charcoal is the most efficacious decontamination method, with very few adverse side effects. Activated charcoal is produced by heating wood pulp, washing it, and then activating it with steam or acid. It has a large surface area for direct adsorption of agents in the gastrointestinal tract. It is usually safe and inexpensive, and it adsorbs most toxins (Box 143.6). This agent should be administered at a dose of 1 to 2 g/kg in overdose patients who are awake and alert or have a protected airway.

Charcoal does not adsorb all poisons. Infrequent complications include intestinal obstruction and aspiration pneumonitis. The effectiveness of activated charcoal has been found in volunteer studies to decrease with time; the greatest benefit occurs within 1 hour of ingestion, and single-dose activated charcoal should not be administered routinely for the management of poisoned patients. Administration of activated charcoal may be considered if a patient has ingested a potentially toxic amount of a poison (which is known to be adsorbed to charcoal) up to 1 hour previously; insufficient data support or exclude its use more than 1 hour after ingestion.18

Multiple-dose activated charcoal (every 4 hours) may be useful for the ingestion of some drugs with enteroenteric enterohepatic circulation (see Box 143.6). Studies have shown decreases in the half-life of these drugs; however, clinical benefit of this approach has not been well established. Repetitive doses of charcoal, 0.25 to 1 g/kg, are given every 4 to 6 hours. Although many studies in animals and volunteers have demonstrated that multiple-dose activated charcoal increases drug elimination significantly, this therapy has not yet been shown in a controlled study to reduce morbidity and mortality. On the basis of experimental and clinical studies, therefore, administration of multiple-dose activated charcoal should be considered if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.19

Not a single study has shown any benefit from the use of cathartics in poisoned patients. Cathartics include magnesium sulfate, sorbitol, and magnesium citrate. Drugs and toxins are usually absorbed within 30 to 90 minutes, and cathartics and laxatives take hours to work. Serious fluid and electrolyte shifts can occur as a result of the use of cathartics, and a few infant deaths have been reported. Complications of cathartics include electrolyte imbalance, dehydration, and hypermagnesemia. Administration of a cathartic alone has no role in the management of a poisoned patient and is not recommended as a method of gut decontamination.20

Whole-bowel irrigation should not be used routinely in the management of a poisoned patient. Although some volunteer studies have shown substantial decreases in the bioavailability of ingested drugs with this method, no controlled clinical trials have been performed, and there is no conclusive evidence that whole-bowel irrigation improves outcome in a poisoned patient.21 Whole-bowel irrigation consists of the administration of a polyethylene glycol solution until the rectal effluent is clear. Whole-bowel irrigation should be reserved for life-threatening intoxications from sustained-release (CR, SR, LA, XL) beta-blockers, calcium channel blockers, lithium, iron, and lead. Most of the time, placement of a nasogastric tube is required for administration. Oral administration of charcoal followed by whole-bowel irrigation is the safest way to decontaminate people whose bodies have been stuffed with packets of illegal drugs. The dose is 20 mL/kg/hr, which translates to about 2 L/hr for adults and 0.5 L/hr for children. The end point is a clear rectal effluent, which usually requires 4 to 6 hours of treatment.

---

**BOX 143.6 Use of Activated Charcoal for Toxic Ingestions**

**Substances Poorly Adsorbed by Activated Charcoal**

- Potassium
- Hydrocarbons, Heavy metals
- Alcohols, Alkali, Acidic
- Iron
- Laxatives (sodium, magnesium, potassium based)
- Solvents

**Contraindications to Use of Activated Charcoal**

- Unprotected airway
- Altered mental status
- Uncooperative patient
- Intestinal obstruction
- Poor gastrointestinal tract function
- Decreased peristalsis
- Ileus
- Bowel obstruction
- Aspiration

**Drugs with Enterohepatic Circulation**

Multiple-dose activated charcoal (every 4 hours) may be useful for some drugs with enterohepatic circulation, such as:

- Antidepressants: nortriptyline, amitriptyline
- Acetylsalicylic acid
- Aminophylline
- Carbamazepine
- Digitalis
- Dapsone
- Phenobarbital
- Phenylbutazone
- Phenytoin
- Quinine
- Theophylline
ENHANCEMENT OF ELIMINATION

Urine alkalinization should be considered first-line treatment in patients with moderately severe salicylate poisoning whose condition does not meet the criteria for hemodialysis. Alkalinization traps weak acids in an ionized state, thereby decreasing their reabsorption. Urine alkalinization increases ion trapping and thus urinary elimination of chlorpropamide, 2,4-dichlorophenoxyacetic acid, diflunisal, fluoride, mecoprop, methotrexate, phenobarbital, and salicylate. If the patient is acidemic, immediate correction with 1 to 2 mEq/kg of sodium bicarbonate can be performed immediately. Then a bicarbonate intravenous infusion of 100 to 150 mEq sodium bicarbonate in 1 L of D,W at 150 to 200 mg/hr. Sodium bicarbonate is administered as an intravenous drip at a rate of 0.5 to 2 mEq/kg/hr after a bolus of 1 to 2 mEq/kg. The dosage should be titrated to keep urine pH at 7.5 to 8.0. Urine pH should be tested every 30 minutes then once an hour to ensure adequate alkalinization. Check serum pH and potassium hourly. Urine alkalinization cannot be recommended as first-line treatment in cases of phenobarbital poisoning, for which multiple-dose activated charcoal is superior.22

In an unstable overdosed patient, consultation with a nephrologist for emergency hemodialysis may be indicated before the results of definitive diagnostic studies or drug level measurements are available. Toxins for which hemodialysis may be useful should have the following features: low molecular weight (<500 D), water solubility, low protein binding (<70% to 80%), and small volume of distribution (<1 L/kg). Toxins for which hemodialysis may be required include methanol, ethylene glycol, boric acid, salicylates, and lithium (Box 143.7).

BOX 143.7 Examples of Agents Removed by Hemodialysis

| Barbiturates | Lithium |
| Boric acid | Methanol |
| Ethylene glycol | Salicylates |
| Isopropanol | Theophylline |

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients who are cleared from a toxicology standpoint should be evaluated by psychiatric services if there is any question of an intentional overdose. Any patient with symptoms should be admitted for observation, and a sitter should be provided if the patient is suicidal. Typically, patients with unknown ingestions are observed for 6 hours; if asymptomatic, they can be released home or to psychiatric services as indicated. Patients should be observed until beyond the expected peak serum concentration or until asymptomatic (or both). Parents of children who have been evaluated for an ingestion or potential ingestion should be counseled about poisoning precautions and given contact information for the poison control center. Specific recommendations are provided in subsequent chapters related to the ingestion of specific toxins.

REFERENCES

Acetaminophen (APAP) is widely available in single-agent preparations, as well as in numerous cold, cough, and pain relief medications. Ingestion of APAP is the most commonly reported exposure to a potentially toxic pharmacologic agent. APAP toxicity is clinically silent up to 24 hours after ingestion. If any abnormalities in vital signs or significant symptoms are present, a coingestant should be suspected. A blood specimen for serum APAP determination should be collected 4 hours after ingestion. The serum APAP result should be applied to the APAP nomogram for determination of the patient’s risk for toxicity. N-Acetylcysteine (NAC) is the antidote for APAP poisoning, and the approach to treatment depends on the timing of the ingestion and the serum APAP level. Oral NAC dosing consists of a loading dose of 140 mg/kg and maintenance dose of 70 mg/kg every 4 hours for 17 doses. An intravenous formulation of NAC is now approved for use and should be given when oral administration is not feasible. The serum APAP level should be measured in any patient with clinical suspicion of an overdose or an attempt at suicide or if a patient with an overdose exhibits altered mental status.

After therapeutic ingestion of APAP, more than 90% is metabolized in the liver to inactive and nontoxic glucuronide and sulfate conjugates that are subsequently excreted in urine. Less than 5% is metabolized by the cytochrome P-450 mixed-function oxidase system to form the highly reactive and toxic intermediate N-acetyl-p-benzoquinone imine (NAPQI). Glutathione quickly reduces NAPQI to a nontoxic metabolite that is eliminated in urine.

After an overdose of APAP, the normal nontoxic glucuronidation and sulfation pathways of metabolism become saturated, which allows more APAP to be metabolized by the cytochrome P-450 system to the toxic metabolite NAPQI. Once available stores of glutathione are diminished, the highly reactive NAPQI binds to intracellular proteins, thereby beginning the cascade of events that lead to cell death. Oxidative drug metabolism by the cytochrome P-450 system to NAPQI is concentrated in zone III (the centrilobular area of the hepatic lobule)—hence the characteristic centrilobular necrosis described with APAP toxicity.

Table 144.1 summarizes the four stages of APAP poisoning. The clinical manifestations of an APAP overdose arise from the hepatotoxicity and resultant complications. Patients, even those who eventually progress to fulminant hepatic failure, are initially asymptomatic. Significant abnormalities in vital signs or clinical findings that become evident soon after ingestion should not be attributed to APAP alone; the emergency physician (EP) should pursue diagnosis and treatment of a coingested agent.

The differential diagnosis for APAP overdose includes other causes of liver damage such as shock liver, acute hepatitis A or B, mushroom exposure (Amanita phalloides), herbal preparations (cascara, chaparral, comfrey, kava, ma-huang), industrial chemicals (carbon tetrachloride, trichloroethylene, paraquat), angiotensin-converting enzyme inhibitors, anabolic steroids, aspirin, ibuprofen, isoniazid, calcium channel blockers, oral contraceptives, and corticosteroids.

Acetaminopenh, Aspirin, and NSAIDs

Heather Long
patients who are seen late after ingestion and already exhibit signs and symptoms of hepatotoxicity or for whom the time of ingestion cannot be readily established, the serum aspartate transaminase (AST) level should also be measured. See Figures 144.2 and 144.3 for guidelines to assess risk after acute and chronic APAP ingestion. Acute ingestion is defined as a single ingestion occurring over a single period shorter than 4 hours.

If there is any clinical suspicion of an overdose, even if the patient does not admit to APAP ingestion or if the patient with an overdose exhibits altered mental status, the serum APAP level should be measured. Approximately 1 in 500 patients who have taken an overdose but do not admit to ingestion of APAP have a potentially hepatotoxic serum APAP concentration.

TREATMENT

Treatment with 50 g of activated charcoal should be considered in patients with large ingestions of APAP or coinfection of APAP and potentially toxic agents that bind to charcoal. N-Acetylcysteine (NAC) is the antidote for APAP toxicity. If given within 8 hours of ingestion, the risk for significant hepatotoxicity secondary to APAP toxicity is low. There does not appear to be a significant advantage to administering NAC within the first 2 or 3 hours after ingestion over giving it later as long as it is within the 8-hour window. See Figures 144.2 and 144.3 for guidelines in determining which patients should be given NAC after acute and chronic APAP ingestion and in managing patient care. NAC is available in both oral and intravenous formulations. In general, both formulations are highly effective and well tolerated. Whether one formulation is superior remains controversial. See Box 144.1 for a comparison of the two formulations and Box 144.2 for dosing regimens.

Patients initially seen longer than 8 hours after ingestion should be treated with NAC on arrival at the emergency department. Whether one formulation is superior remains controversial. See Box 144.1 for a comparison of the two formulations and Box 144.2 for dosing regimens.
department and their serum APAP and AST levels measured. If the APAP level is above the treatment threshold on the nomogram (see Fig. 144.1), treatment with NAC should continue. If not and the patient has no signs or symptoms consistent with hepatotoxicity, NAC should be discontinued. NAC improves morbidity and mortality even if given late after ingestion and even if administered to patients in fulminant hepatic failure after APAP ingestion. Rarely, patients with very high APAP levels or those seen late after ingestion may require a prolonged course of NAC. The EP should contact the regional poison control center for further assistance in managing patients with APAP overdose.

**PEDIATRIC CONSIDERATIONS**

Children should be evaluated for potential risk for hepatotoxicity after both acute exposure and repeated excessive dosing. Serum APAP and AST levels should be measured in those

---

**BOX 144.1 Oral versus Intravenous Administration of N-Acetylcysteine**

**Oral**

Induces nausea or vomiting in more than 50% of patients
Inexpensive
Ease of dosing schedule
Safer than intravenous administration

**Intravenous**

Considered the preferred route in following settings:
- Fulminant hepatic failure
- Patient unable to tolerate oral administration

The preparation must be adjusted for children weighing less than 40 kg
Complicated dosing regimen
Risk for anaphylactoid reactions
Fig. 144.3 Risk assessment and management of chronic acetaminophen (APAP) poisoning. AST, Aspartate aminotransferase; INR, international normalized ratio; NAC, N-acetylcysteine; PT, prothrombin time; WNL, within normal limits.

**Assess risk for APAP poisoning**

Signs and/or symptoms of hepatotoxicity present?

**Pediatrics**

- Ingestion of >75 mg/kg APAP in a 24-hour period in association with acute febrile illness, malnourishment, or chronic treatment with anticonvulsants or isoniazid
- Ingestion of >150 mg/kg APAP in a 24-hour period otherwise

**Adults**

- Ingestion of >4 g APAP in a 24-hour period in association with acute febrile illness, malnourishment, chronic alcohol use, or chronic treatment with anticonvulsants or isoniazid
- Ingestion of >7.5 g in a 24-hour period

If any of the above criteria, or signs and symptoms, obtain liver profile, PT, INR, and chemistry profile

- APAP level falls on or above treatment line of nomogram based on time of last dose
- AST > 2 times normal
- AST is elevated and patient is symptomatic
- AST is elevated and APAP > 10 mcg/mL
- Patient is asymptomatic, APAP < 10 mcg/mL, AST < 2 times normal
- APAP level is appropriate for time of last dose and AST is normal

High risk for hepatotoxicity

Begin NAC treatment

Low risk for hepatotoxicity

Patient may be discharged with follow-up and instructions to return for signs of hepatotoxicity

Minimal risk

**BOX 144.2 Dosing Schedule for N-Acetylcysteine (NAC)**

**Oral (Adult and Pediatric)**

- Loading dose (adult and pediatric): 140 mg/kg
- Maintenance dose: 70 mg/kg every 4 hours for 17 doses (next 68 hours)
- May be chilled or diluted with water, soda, or juice to ease administration

**Intravenous**

**Adult**

- Loading dose: 150 mg/kg in 200 mL of 5% dextrose in water (D5W) infused over a 60-minute period to reduce the risk for an anaphylactoid reaction
- Second dose: 50 mg/kg in 500 mL D5W over a 4-hour period
- Third dose: 100 mg/kg in 1 L D5W over a 16-hour period

**Pediatric (<40 kg)**

- For patients weighing more than 10 kg, follow the package insert or regimen below
- For infants less than 10 kg, dilute IV NAC to a 2% solution and then follow the dosing regimen below: Remove 50 mL from a 500-mL bag of D5W, and add 50 mL IV NAC (20%) to 450 mL D5W to create a 2% solution
- Loading dose: 7.5 mL/kg (150 mg/kg) of a 2% solution over a 1-hour period
- Second dose: 2.5 mL/kg (50 mg/kg) of a 2% solution over a 4-hour period
- Third dose: 5 mL/kg (100 mg/kg) of a 2% solution over a 16-hour period

**PREGNANT PATIENT**

Oral NAC is routinely given to pregnant patients after potentially toxic APAP exposure and seems to be safe and effective. NAC appears to be safe for the fetus regardless of whether the mother receives the NAC orally or intravenously; however,
BOX 144.3 Indications for Intensive Care Unit Admission or Transfer to a Liver Transplantation Center for a Patient with Hepatotoxicity

Severe hepatotoxicity:
- Elevated aspartate transaminase and alanine transaminase values
- Prolonged prothrombin time
- Elevated blood urea nitrogen or creatinine value
- Metabolic acidosis
- Hypoglycemia
- Signs of hepatic encephalopathy

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients deemed to be at risk for hepatotoxicity should be treated with oral NAC within 8 hours of ingestion or as soon as possible thereafter and be admitted to the hospital for further medical and psychiatric evaluation as indicated. Patients with signs of severe hepatotoxicity, hepatic encephalopathy, or fulminant hepatic failure should be admitted to the intensive care unit (ICU), and early contact should be made with both the poison control center and a liver transplantation center (Box 144.3).

ASPIRIN (SALICYLATES)

KEY POINTS

- Methyl salicylate is found in topical liniments and in oil of wintergreen.
- Aspirin toxicity in adults is characterized by a mixed respiratory alkalosis and metabolic acidosis.
- Acute toxicity is marked by tachypnea or hyperpnea, tachycardia, nausea, vomiting, and progressive central nervous system deterioration.
- Chronic aspirin toxicity is seen most commonly in the elderly and is frequently misdiagnosed as sepsis or dementia.
- Aspirin toxicity is treated with multiple-dose activated charcoal, fluid resuscitation, urine alkalinization, and hemodialysis.

EPIDEMIOLOGY

Aspirin (acetylsalicylic acid [ASA]) is found in single-agent preparations; in numerous cold, cough, and pain relief formulations; and in topical ointments and topical wart removal agents. Bismuth salicylate is included in the antidiarrheal medicine Pepto Bismol, and methyl salicylate is used in varying concentrations in liniments (30%) and oil of wintergreen (up to 100%). The incidence of unintentional salicylate poisoning has diminished with the growing use of APAP and nonsteroidal antiinflammatory drugs (NSAIDs) and with the increasing use of APAP rather than aspirin in children with viral illnesses to avoid Reye syndrome. In the United States, analgesics are the substances most frequently involved in human poison exposure for all age groups and the third most frequently involved substances in both pediatric (5 years and younger) and adult (>19 years) exposures. Aspirin alone caused 63 deaths in the United States in 2007 out of a total of 1597 fatalities from poisoning.

PATHOPHYSIOLOGY

Salicylate toxicity in adults is characterized by a mixed respiratory alkalosis and metabolic acidosis. Salicylates stimulate the respiratory center in the brainstem, which causes hyperventilation and a primary respiratory alkalosis. In addition, salicylates cause an anion gap metabolic acidosis, probably through several mechanisms. They uncouple oxidative phosphorylation, which leads to an accumulation of hydrogen ions, blocks the production of adenosine triphosphate, and favors the production of lactate. Salicylate toxicity interferes with the renal elimination of sulfuric and phosphoric acids and induces fatty acid metabolism, with the generation of α-hydroxybutyric acid and acetoacetic acid.

In children, primary metabolic alkalosis is not commonly seen, either because they do not sustain the hyperventilation that adults do or because of a delay in medical care. In adults, the primary respiratory alkalosis may be blunted or absent as a result of salicylate-induced acute lung injury (noncardiogenic pulmonary edema), respiratory fatigue (a sign of severe toxicity), or concomitant ingestion of a central nervous system depressant.

Salicylate toxicity may induce acute lung injury, classically described as “noncardiogenic pulmonary edema.” The mechanisms are unclear. Hypoxia is presumed to contribute to the pulmonary hypertension and release of vasoactive factors, which results in greater capillary permeability and more exudate in the interstitial and alveolar spaces.

The increased metabolic state associated with salicylate poisoning results in hypoglycemia and ketosis.

Otototoxicity, characterized by hearing loss and tinnitus, is a predictable manifestation of salicylate toxicity that occurs with serum ASA concentrations of 25 to 40 mg/dL. The cause is unknown, but it is postulated that salicylate has effects on glucose and protein metabolism that involve the endolymph and perilymph and thus alter nerve transmission.

PRESENTING SIGNS AND SYMPTOMS

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis for salicylate toxicity includes diabetic ketoacidosis, dementia, withdrawal syndromes, meningitis or encephalitis, acetaminophen overdose, toxic alcohol ingestion, lactic acidosis, and iron toxicity. See Table 144.3 for laboratory and diagnostic tests useful in evaluating salicylate toxicity.

**TREATMENT**

The mainstays of therapy after salicylate ingestion are multiple-dose activated charcoal, fluid and electrolyte replenishment, urine alkalinization, and in cases of severe toxicity, hemodialysis. Table 144.4 lists guidelines for managing and treating patients with salicylate toxicity, instructions on urine alkalinization, and indications for hemodialysis. The EP should contact the renal service early in cases of severe toxicity and consult with the regional poison control center for continued assistance soon after patient arrival.
FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients with signs or symptoms of salicylate toxicity should be admitted to the hospital for continued monitoring of their clinical condition and serial laboratory evaluations. Patients with signs and symptoms of serious toxicity should be admitted to the ICU and evaluated early by the renal service for possible hemodialysis.

NONSTERoidal ANTIinFLAMMATORY DRUGS

KEY POINTS
- Nonsteroidal antiinflammatory drugs (NSAIDs) are a large class of drugs that include the over-the-counter drugs ibuprofen, naproxen, and ketoprofen.
- Nausea, vomiting, epigastric pain, and mild central nervous system depression are the most common clinical manifestations of NSAID poisoning.
- NSAID toxicity is usually mild and should be managed with gastrointestinal decontamination and supportive care.

NSAIDs are a large class of drugs, and exposure to and overdose of NSAIDs are common given their widespread use. Ibuprofen, naproxen, and ketoprofen are available over the counter. Ibuprofen accounts for 70% to 80% of all NSAID exposures reported to U.S. poison control centers. In 2007, calls to U.S. poison control centers (as documented by the National Poison Data System of the American Association of Poison Control Centers) included 307,590 cases involving NSAIDs (other than salicylates). Of these calls, 205,245 cases were found to be due to single exposures. More than 100,000 NSAID calls involved coingestants.

PATHOPHYSIOLOGY

All NSAIDs competitively inhibit cyclooxygenase (COX), thereby preventing the formation of prostaglandins, prostacyclin, and thromboxane. Unlike salicylates, NSAIDs reversibly bind to COX. There are two isoforms: COX-1 and COX-2. The analgesic and antiinflammatory properties are attributed to inhibition of COX-2. Most of the adverse effects and the acute toxicity of NSAIDs are attributed to inhibition of COX-1.

NSAIDs directly irritate the gastrointestinal mucosa; COX-1–mediated prostaglandin inhibition further contributes to gastrointestinal irritation, ulceration, and perforation.

Rarely, NSAID toxicity induces an anion gap metabolic acidosis associated with elevated serum lactate. This
condition is attributed to NSAID metabolites, which are weak acids, rather than to COX inhibition and is favored by relative hypotension and hypoxia.

NSAID-induced renal toxicity is due to inhibition of prostaglandin and occurs in the setting of low intravascular volume such as seen with hypovolemia, congestive heart failure, cirrhosis, or intrinsic renal disease.

Via inhibition of thromboxane A₂, NSAIDs decrease platelet aggregation. Other idiosyncratic reactions associated with some NSAIDs are hemolytic anemia, aplastic anemia, agranulocytosis, and thrombocytopenia.

NSAID-induced COX inhibition is associated with anaphylactoid reactions. Acute bronchospasm may develop within minutes to hours of NSAID ingestion in adult patients with asthma and chronic urticaria or nasal polyps. Agents that block 5-lipoxygenase or leukotriene receptors may prevent adverse reactions.

**PRESENTING SIGNS AND SYMPTOMS**

See Box 144.5 for the signs and symptoms of NSAID toxicity. Gastrointestinal manifestations are the most common; rare findings after large ibuprofen ingestions include metabolic acidosis, coma, bradycardia, and hypotension.¹²

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis for NSAID toxicity includes other ingestions such as APAP or salicylate, chronic anemia, anxiety, delirium or dementia, peptic ulcer disease, lactic acidosis, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

Serum NSAID concentrations are not readily available from hospital laboratories and are not clinically useful. After a large overdose or in symptomatic patients, serum electrolyte, blood urea nitrogen or creatinine, serum bicarbonate, and arterial blood gas measurements should be obtained.

**TIPS AND TRICKS**

- Measure serum acetaminophen in all patients with suspected overdose.
- Initiate treatment with N-acetylcysteine in patients seen late after an acetaminophen overdose.
- Initiate early contact with the poison control center and liver transplant center for patients with severe acetaminophen toxicity.
- Consider chronic salicylate poisoning in elderly patients with altered mental status.
- Initiate treatment with sodium bicarbonate and contact the renal service for potential hemodialysis in patients with salicylate poisoning.
- Beware of the risk of worsening the acidemia during intubation of patients with severe salicylate poisoning, and ensure adequate ventilation.

**TREATMENT**

Life-threatening complications after an NSAID overdose are rare. Treatment consists of supportive care, fluid and electrolyte replacement, and gastric decontamination with activated charcoal. Asymptomatic patients should receive one dose of activated charcoal and be observed for 6 hours after ingestion.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients who remain asymptomatic after 6 hours of observation may be further evaluated by the psychiatric service or may be discharged with arrangements for follow-up and instructions to return if gastrointestinal or central nervous system signs and symptoms develop. For symptomatic patients, the diagnostic tests already described should be performed, and the patients should be admitted to the hospital for further observation and evaluation.

Anticholinergics

Jessica A. Fulton and Lewis S. Nelson

KEY POINTS

- Antimuscarinic poisoning syndrome is a more appropriate description than anticholinergic overdose because only the muscarinic receptors, not the nicotinic acetylcholine receptors, are involved. In this chapter the term anticholinergic will be used for consistency and is specifically meant to indicate antimuscarinic.
- Anticholinergic agents antagonize the neurotransmitter acetylcholine at both central and peripheral muscarinic acetylcholine receptors, which leads to altered mental status, mydriasis, tachycardia, urinary retention, ileus, and dry, flushed skin.
- The diagnosis of anticholinergic syndrome is largely clinical and should include physical examination, fingerstick serum glucose measurement, and an electrocardiogram.
- Anticholinergic syndrome is a key clinical finding leading to the diagnosis of poisoning by tricyclic antidepressants (a subset of antimuscarinic agents).
- Basic treatment involves supportive care of the vital signs, activated charcoal, benzodiazepines for agitation, sodium bicarbonate for a QRS complex longer than 100 msec or wide-complex tachycardia, and phystostigmine for consequential central and peripheral anticholinergic (antimuscarinic) manifestations, if appropriate.

EPIDEMIOLOGY

Because anticholinergic toxicologic syndrome (toxidrome) is common, recognition of its associated signs and symptoms is a necessary clinical skill. It occurs following exposure to many seemingly unrelated agents, many of which are available without prescription or used in patients with a propensity toward self-harm (Box 145.1). For example, according to data from the American Association of Poison Control Centers, 25,788 single exposures to diphenhydramine alone occurred in 2008, with 201 major outcomes and 3 deaths.

PATHOPHYSIOLOGY AND PHARMACOLOGY

Acetylcholine is the neurotransmitter released from cholinergic nerve endings in the central (brain and spinal cord) and peripheral (autonomic and somatic) nervous systems. In the autonomic (sympathetic and parasympathetic) nervous system, acetylcholine is released from all preganglionic neurons, as well as from postganglionic parasympathetic neurons. Degradation of acetylcholine by the enzyme acetylcholinesterase occurs in the synapse between the presynaptic and postsynaptic membranes.

There are two types of postsynaptic acetylcholine receptors: nicotinic and muscarinic. Nicotinic acetylcholine receptors are ion channels that open in response to stimulation. Found throughout the central nervous system (CNS) (most abundantly in the spinal cord), they are the postsynaptic receptors in the preganglionic sympathetic and parasympathetic neurons. Additionally, these receptors are found in the somatic nervous system at postganglionic skeletal neuromuscular junctions that mediate muscle contraction, as well as in postganglionic neurons of the adrenal medulla, which are subsequently responsible for the release of epinephrine and norepinephrine.

Muscarinic acetylcholine receptors are linked to G proteins to execute their postreceptor effects. They are found primarily in the CNS (most abundantly in the brain). They are also present at effector organs innervated by postganglionic parasympathetic neurons. Stimulation of these end-organs, either pharmacologically or through enhanced neuronal output, results in miosis, lacrimation, salivation, bronchospasms, bronchorrhea, bradydysrhythmia, urination, and increased gastrointestinal motility (Table 145.1). Finally, muscarinic receptors are located in sweat glands innervated by postsynaptic sympathetic neurons and cause diaphoresis when stimulated.

Muscarinic acetylcholine receptor antagonists competitively inhibit muscarinic acetylcholine receptors. These agents cause the classic anticholinergic poisoning syndrome, which may perhaps be more appropriately designated the antimuscarinic poisoning syndrome because nicotinic acetylcholine receptors are not affected. Muscarinic receptors in different organs are not equally sensitive to antimuscarinic agents.

Tricyclic antidepressants are a unique subset of antimuscarinic agents that deserve special attention. Their antidepressant effect is achieved pharmacologically through blockade of the reuptake of norepinephrine, dopamine, and serotonin in the CNS. Additionally, tricyclic antidepressants interact with other channels and receptors and cause considerably more profound clinical toxicity in overdose than occurs with most other agents that exhibit anticholinergic effects. Adverse effects of a tricyclic antidepressant overdose include competitive inhibition at both central and peripheral muscarinic acetylcholine receptors (antimuscarinic poisoning syndrome); histamine receptor antagonism (sedation); sodium channel blockade in the myocardium (widening of the QRS complex...
Anticholinergic syndrome can be caused by many agents, including atropine, diphenhydramine, and scopolamine.

or wide-complex dysrhythmias, atrioventricular block, QT prolongation, and rightward shift of the terminal 40-msec QRS axis on an electrocardiogram [ECG], as well as negative inotropy leading to hypotension; α-adrenergic receptor antagonism on vascular smooth muscle (vasodilation leading to hypotension); and although the mechanism of this effect is unclear, γ-aminobutyric acid (GABA) antagonism (seizures). In the right clinical setting, anticholinergic syndrome is a key clinical finding leading to the diagnosis of tricyclic antidepressant poisoning (Table 145.2).

### PRESENTING SIGNS AND SYMPTOMS

Central inhibition of muscarinic acetylcholine receptors results in confusion, disorientation, psychomotor agitation, ataxia, myoclonus, tremor, picking movements, abnormal speech, visual and auditory hallucinations, psychosis, seizures, cardiovascular collapse, and coma.

Inhibition of postsynaptic sympathetic muscarinic acetylcholine receptors in the sweat glands, as well as vasodilation of peripheral blood vessels, gives rise to dry, flushed skin. Inability to sweat, particularly in the presence of altered CNS regulation, may lead to hyperthermia. Inhibition of these receptors in the salivary glands results in dry mucous membranes, whereas inhibition of these receptors in the eye (which cause pupillary constriction when activated) leads to paralysis of the sphincter muscle of the iris and the ciliary muscle of the lens with subsequent mydriasis, cycloplegia, and blurred vision. Tachycardia is caused by inhibition of postsynaptic parasympathetic muscarinic acetylcholine receptors on the vagus nerve. Dysrhythmias may be caused by antimuscarinic agents that possess additional pharmacologic effects. For example, agents that produce sodium channel blockade in the myocardium (i.e., tricyclic antidepressants, diphenhydramine, pheniramine, orphenadrine, pyrilamine) cause widening of the QRS complex or wide-complex dysrhythmias, atrioventricular block, QT prolongation, and rightward shift of the terminal 40-msec QRS axis on the ECG, as well as negative inotropy leading to hypotension. Inhibition of postsynaptic parasympathetic muscarinic acetylcholine receptors in the bladder results in urinary retention and overflow incontinence, and in the bowel it causes adynamic ileus.

Frequently, patients with anticholinergic (antimuscarinic) poisoning do not have all the previously mentioned characteristics of the classic syndrome, especially the elderly and patients with organic brain syndrome, in whom central anticholinergic (antimuscarinic) poisoning syndrome is often more pronounced than or outlasts the peripheral syndrome.

See Tables 145.1 and 145.2, which detail the pathophysiology associated with the signs and symptoms of antimuscarinic poisoning syndrome and tricyclic antidepressants.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

#### DIAGNOSTIC FEATURES

Patients who overdose with an anticholinergic (antimuscarinic) agent often have sufficient clinical findings to make the diagnosis apparent. However, the symptoms and signs in others may be less overt, and thus a substantially broader differential diagnosis is required.

Although patients with both adrenergic (sympathomimetic) and anticholinergic (antimuscarinic) poisoning may exhibit confusion, disorientation, psychomotor agitation, seizures, flushed skin, hyperthermia, mydriasis, and tachycardia, the two syndromes may be differentiated through examination of the skin and observation of the symptoms associated with the altered mental status. Patients with anticholinergic poisoning have dry skin and mucous membranes, and the alteration in mental status is characterized by mumbling speech, delirium, and tactile or visual hallucinations. In contrast, patients poisoned by sympathomimetic agents, such as cocaine toxicity, are typically, though not always, diaphoretic with agitated or violent behavior and hallucinations that are more commonly paranoid.

Multiple other toxicologic entities are associated with autonomic dysfunction (i.e., dysregulation of the heart rate, blood pressure, temperature, gastrointestinal secretion, metabolic and endocrine responses to stress). Acute withdrawal syndromes may be differentiated from anticholinergic (antimuscarinic) syndrome by a history of recent cessation of ethanol or another sedative-hypnotic agent, serotonin syndrome may be differentiated by a history of recent (minutes to hours) exposure to a serotonergic agent, and neuroleptic malignant syndrome may be differentiated by a history of exposure (within 3 to 9 days) to an agent capable of producing central dopamine blockade. Drug-induced psychosis mimicking central anticholinergic syndrome may be due to hallucinogens, phencyclidine, amphetamines, or corticosteroids.

Medical diseases that produce confusion, seizures, and tachycardia, such as hypoxia, hypoglycemia, and heat stroke, or those that cause hyperthermia, hypertension, tachycardia, and mydriasis, such as thyrotoxicosis and pheochromocytoma, may also be confused with anticholinergic toxicity.

Finally, diseases that may be manifested similar to central anticholinergic syndrome include schizophrenia and other psychotic disorders, cerebral vasculitis, CNS infection (e.g., encephalitis), sepsis, and psychiatric disease.

### Diagnostic Testing

In the setting of anticholinergic (antimuscarinic) poisoning, results of the fingerstick serum glucose test and pulse oximetry analysis should be normal.

The ECG typically demonstrates sinus tachycardia. Some agents with anticholinergic (antimuscarinic) effects also have type IA antidysrhythmic effects that result in blockade of myocardial sodium channels. The blockade is seen on the ECG as prolongation of the QRS interval. Such agents include diphenhydramine, cyclobenzaprine, carbamazepine, and the tricyclic antidepressants.

With tricyclic antidepressant overdose in particular, the extent of prolongation of the QRS interval on an ECG is especially useful in predicting the severity of toxicity.

---

**FACTS AND FORMULAS**

A QRS duration shorter than 100 msec predicts that no serious clinical toxicity will occur, a QRS duration longer than 100 msec is associated with a 30% incidence of seizures, and a QRS duration longer than 160 msec is associated with a 50% likelihood of the development of ventricular dysrhythmia. Additionally, an R wave in lead aVR measuring 3 mm or greater or a terminal 40-msec right axis deviation between 130 and 270 degrees is a predictor of tricyclic antidepressant–induced toxicity.

---

**RED FLAGS**

**Cautions for Physicians**

Physostigmine is contraindicated in patients after a tricyclic antidepressant overdose with a QRS interval longer than 100 msec because it may cause cardiac arrhythmias and profound hypotension.

Flumazenil should not generally be administered to patients with anticholinergic (antimuscarinic) toxicity because it may cause seizures or other complications.

Failure to become cholinergic (bradycardia, bronchorrhea, diaphoretic, drooling) after the administration of physostigmine is essentially diagnostic of anticholinergic toxicity.

Physostigmine will prolong the action of drugs metabolized by cholinesterases, such as succinylcholine. A nondepolarizing agent should be used instead.

Prolonged agitation and seizures can lead to the development of acidosis and rhabdomyolysis. Measurement of serum creatine phosphokinase and urine myoglobin aids in the recognition of patients at risk for the development of acute renal failure.

### Treatment

Most patients with anticholinergic (antimuscarinic) toxicity can be treated adequately with general supportive care of the airway, breathing, and circulation, followed by frequent reassessment and close observation (Fig. 145.1). To avoid the risk for aspiration, activated charcoal (1 g/kg) is recommended only for patients who are capable of spontaneously drinking and protecting their own airway. It may also be administered cautiously via a nasogastric tube to patients who are endotracheally intubated. Because anticholinergic (antimuscarinic) agents may slow gastrointestinal transit, activated charcoal may be useful several hours after ingestion. The specific role of activated charcoal in most of these poisonings has not been studied.

The initial therapy for cardiovascular toxicity secondary to sodium channel blockade is hypertonic sodium bicarbonate in 1- to 2-mEq/kg boluses. Treatment with sodium bicarbonate is indicated for patients with a QRS complex longer than 100 to 120 msec or a wide-complex or ventricular tachycardia until the abnormality is reversed or serum pH reaches 7.55. The ECG should be repeated within 60 seconds after a bolus of sodium bicarbonate to check for narrowing of the QRS complex. If narrowing has occurred, a continuous infusion at 1.5 times the maintenance intravenous fluid rate (three ampules [132 mEq] of sodium bicarbonate in 1 L of 5% dextrose in water [D5W]) should be administered. Profound cardiovascular toxicity may require more aggressive interventions, such as the initiation of vasopressors or use of an intraaortic balloon pump.

Agitation should be addressed aggressively to prevent the development of more serious sequelae, such as hyperthermia, acidosis, and rhabdomyolysis. It is best controlled with benzodiazepines. The emergency physician should start with standard doses (i.e., diazepam, 5 to 10 mg intravenously) and repeat them until sedation (relief of agitation, myoclonus, tremor, picking movements, abnormal speech, and hallucinations) is achieved. Administration of physostigmine should also be considered for the treatment of agitation caused by an anticholinergic agent (see later).

Anticholinergic (antimuscarinic) agent–induced seizures should also be treated with standard doses of benzodiazepines (i.e., lorazepam, 2 mg intravenously) or with physostigmine. If this therapy fails, barbiturates or other GABAergic anticonvulsants should be administered. Phenytoin is rarely useful for toxin-induced seizures.

Patients with rhabdomyolysis should be administered saline intravenously at a rate sufficient to maintain brisk urine output (generally 3 to 5 mL/kg/hr after any lost intravascular volume has been replaced). If urinary pH is less than 6.0, urine alkalization is necessary and is achieved with the use of a sodium bicarbonate infusion at 1.5 times the maintenance intravenous fluid rate (three ampules [132 mEq] of sodium bicarbonate in 1 L of D5W). Serum pH must be monitored during the sodium bicarbonate infusion, which should be stopped if the pH reaches 7.55 or higher.
Fig. 145.1 Algorithm for the recognition and treatment of anticholinergic toxicity. CPK, Creatine phosphokinase; D5W, 5% dextrose in water; ECG, electrocardiogram; IV, intravenous line; TCA, tricyclic antidepressant.
ANTIDOTAL THERAPY—PHYSOSTIGMINE
Physostigmine is a tertiary amine carbamate that penetrates into the CNS. It reversibly inhibits cholinesterases in both the central and peripheral nervous systems, thereby allowing acetylcholine to accumulate within the synapse. Accumulation of acetylcholine directly antagonizes the anticholinergic effects of antimuscarinic agents.

In the setting of a clear diagnosis of anticholinergic toxicity, physostigmine should be administered. It is beneficial in the treatment of agitation and delirium and also shortens the time to recovery after agitation. This agent should not be given once a benzodiazepine has been administered because the end point of clear mental status has been lost.7

During and immediately after the administration of physostigmine, patients must be monitored for early signs of cholinergic toxicity, such as diaphoresis and slowing of the heart rate. Atropine should be kept at the bedside and should be given in titrated doses if needed for cholinergic toxicity (development of bronchorrhea, hypoxia, bradycardia).

Physostigmine is indicated for patients with central (and perhaps peripheral) anticholinergic manifestations. It is contraindicated in patients with a QRS interval longer than 100 msec if the history suggests overdose of tricyclic antidepressant or other cardiotoxic agents. The latter contraindication is based on two case reports of patients with tricyclic antidepressant overdose in whom asystole developed after the administration of physostigmine. The cause of the asystole was theorized to be physostigmine-induced bradycardia that resulted in cardiac conduction defects and decreased cardiac output in the presence of tricyclic antidepressant–induced sodium channel blockade.9 Other contraindications to the use of physostigmine are bronchospastic disease, peripheral vascular disease, intestinal or bladder obstruction, intraventricular conduction defects, and atrioventricular block.

Physostigmine is administered intravenously over a 5-minute period, 1 to 2 mg in adults and 0.02 mg/kg (maximum of 0.5 mg) in children. Its onset of action occurs within minutes.9 This initial dose can be repeated in 5 to 10 minutes if an adequate response is not achieved and muscarinic effects are not noted. Failure of the patient to become cholinergic after the administration of physostigmine is essentially diagnostic of anticholinergic toxicity. Although the total effective dose of physostigmine depends on the individual, as well as the dose and duration of action of the anticholinergic (antimuscarinic) agent, 4 mg is usually a sufficient dose for most patients.10 The half-life of physostigmine is 16 minutes, and its usual duration of action exceeds 1 hour.11

Adverse effects may occur if physostigmine is administered rapidly, in an excessive dose, or in the absence of an anticholinergic (antimuscarinic) agent. In all these instances, an excess of acetylcholine occurs at various sites within the body and has various effects, as follows:

- At nicotinic receptors: muscle fasciculations, weakness, and paralysis
- At muscarinic receptors: bronchospasm, bronchorrhea, bradycardia, salivation, lacrimation, urination, defecation, and emesis
- At CNS sites: anxiety, dizziness, tremors, confusion, ataxia, coma, and seizures

Accordingly, overdoses of physostigmine may require atropine to control the bronchial secretions, and mechanical ventilation may be needed for neuromuscular weakness because no specific antidote is available for the excess nicotinic activity.

Additionally, it is important to note that when other cholinergic agents are used concurrently with physostigmine, the effects may be additive. Examples of such agents are pilocarpine, carbamates, organophosphates, pyridostigmine, and depolarizing neuromuscular blocking agents. Because physostigmine is an acetylcholinesterase inhibitor, it also prolongs the action of drugs metabolized by plasma cholinesterases, such as cocaine, succinylcholine, and mivacurium.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients in whom the anticholinergic toxicity resolves—who therefore do not require intervention for a period of 6 hours—and who have no evidence of complications of toxicity (e.g., aspiration pneumonia, rhabdomyolysis) may be medically

Insecticides, Herbicides, and Rodenticides

Robert D. Cannon and Anne-Michelle Ruha

KEY POINTS

- Organophosphorus and carbamate poisonings cause excessive stimulation of muscarinic and nicotinic receptors by acetylcholine, which can potentially lead to life-threatening bronchorrhea and bronchospasm.
- Aggressive airway management and liberal use of atropine are important in the management of both organophosphorus and carbamate poisoning.
- Only a nondepolarizing neuromuscular blocker, such as vecuronium or rocuronium, should be used for intubation. Succinylcholine is metabolized by plasma cholinesterase, and prolonged paralysis may result if it is used in the setting of organophosphate poisoning.
- Timely administration of pralidoxime is key to the treatment of organophosphorus poisoning, but pralidoxime is not indicated for carbamate poisoning.
- Unintentional pediatric ingestion of 4-hydroxycoumarins (superwarfarins) accounts for the vast majority of rodenticide exposures and rarely results in toxicity.
- Ingestion of an anticoagulant rodenticide should be considered when a child younger than 6 years has an elevated prothrombin time or bleeding without another explanation.
- The prothrombin time should be measured at 24 and 48 hours after large ingestions of 4-hydroxycoumarins.
- Because no specific antidote or pharmacologic intervention has proved beneficial in treating paraquat or diquat poisoning, early decontamination is the most important step.

Insecticides

ORGANOPHOSPHORUS COMPOUNDS AND CARBAMATES

EPIDEMIOLOGY

Organophosphate (OP) compounds and carbamates are used extensively worldwide for agricultural, industrial, and domestic pest control and, as a result, represent a significant public health issue in the developing world. An estimated 3 million poisonings and more than 200,000 deaths occur from OP compounds each year worldwide. In the United States in 2008, 4642 exposures to OP compounds and 2644 exposures to carbamates were reported to the National Poison Data System of the American Association of Poison Control Centers.

PATHOPHYSIOLOGY

The clinical severity and toxicodynamics vary according to the agent, the route of absorption, and whether the exposure was intentional. Regardless of these factors, the toxicologic mechanism of acetylcholinesterase (AChE) inhibition remains consistent. The end result is an excess of the neurotransmitter acetylcholine (ACh), which results in overstimulation of muscarinic and nicotinic receptors and production of a cholinergic toxidrome.

Under normal circumstances, ACh is hydrolyzed by AChE to yield acetic acid and choline. In the presence of OP insecticides, AChE is phosphorylated, whereas in the presence of carbamate insecticides, the enzyme is carbamylated. As a result, the rate of regeneration of active AChE is slowed, and its function is inhibited. Within 24 to 72 hours of OP poisoning, an alkyl group may dissociate from the AChE-OP complex and thereby result in “aging” of the AChE. Once aging occurs, reactivation of AChE is no longer possible, and only synthesis of new enzyme can restore activity. In the case of carbamate poisoning, breakdown of the carbamate-AChE complex occurs much more rapidly and aging does not occur.

ACh accumulates in the autonomic nervous system at postganglionic muscarinic (parasympathetic and sympathetic) receptors and preganglionic nicotinic (sympathetic) receptors. It also accumulates at the neuromuscular junction and in the central nervous system (CNS). Overstimulation of these receptors is responsible for the cholinergic toxidrome seen with OP and carbamate insecticide poisoning (Table 146.1).

PRESENTING SIGNS AND SYMPTOMS

The onset of symptoms can occur within minutes after massive exposure and intentional ingestions or be delayed up to 12 hours after accidental dermal, inhalational, or oral exposure in the occupational arena. Clinical effects may also be somewhat delayed because of the need for bioactivation of...

some OP insecticides after absorption (e.g., malathion). The mnemonic SLUDGE (salivation, lacrimation, urination, defecation, gastric secretions, emesis) has traditionally been used to describe the cholinergic toxidrome. However, the mnemonic DUMBBELLS (defecation, urination, miosis, bronchorrhea, bradycardia, emesis, lacrimation, salivation) is probably more appropriate because it includes the life-threatening conditions bronchorrhea and bradyarrhythmias, as well as miosis, the distinguishing feature.

The clinical effects are summarized in Table 146.1; only caveats in the clinical findings are emphasized here. Bronchorrhea occurs commonly with moderate to severe poisonings\(^4\) and can progress to pulmonary edema and respiratory failure. Miosis in the setting of cholinergic symptoms is fairly specific for OP and carbamate insecticide poisoning and may help make the diagnosis. Unfortunately, it is not consistently present.

Although the parasympathetic muscarinic effects are most often emphasized, certain sympathetic effects may predominate. Sinus tachycardia is more common than bradycardia,\(^4,5\) and mydriasis may even be seen.\(^5\) Nicotinic effects often predominate in mild cases and occur early in severe cases. Excessive nicotinic stimulation at the neuromuscular junction has effects that resemble the actions of a depolarizing neuromuscular blocking agent. Therefore, patients with OP or carbamate insecticide poisoning may exhibit muscle fasciculations and weakness. Paralysis occurs as the toxicity worsens, and the primary cause of death in acute poisonings is probably respiratory arrest secondary to paralysis and bronchorrhea. One to 3 days after apparent resolution of the symptoms, patients may experience profound weakness and paralysis of the proximal muscles, neck flexor muscles, and cranial nerves. This development, termed the intermediate syndrome,\(^6\) is probably explained by ongoing AChE inhibition (Box 146.2).

Finally, carbamates produce peripheral effects similar to those of OP compounds, but generally to a much lesser extent. A distinguishing clinical feature of carbamate toxicity is the paucity of central effects, which is secondary to their poor penetration of the CNS.

### Differential Diagnosis and Medical Decision Making

A detailed history in a patient with signs and symptoms of cholinergic excess often elucidates exposure to OP or carbamate insecticides. The diagnosis of OP or carbamate insecticide poisoning is therefore usually straightforward; however, certain clinical aspects may be mimicked by other entities. Table 146.2 is a partial list of other agents or diagnoses to consider.

All patients with potential OP poisoning should undergo erythrocyte (red blood cell [RBC], or true) cholinesterase and plasma (pseudo) cholinesterase measurement from specimens obtained after arrival at the emergency department (ED). Though not often useful or necessary for making a diagnosis in the ED, the results of this measurement may help guide continued therapy. RBC cholinesterase hydrolyzes ACh and correlates with toxicity, whereas plasma cholinesterase is the first to decline and may be a more sensitive marker of exposure.\(^7\) Both substances should be measured because one may exhibit greater inhibition than the other, depending on the specific OP to which the patient was exposed. Box 146.3 summarizes the tests that may be helpful in evaluating a patient with moderate to severe toxicity.

Cholinesterase values may prove useful in diagnosing OP toxicity if the history or findings on physical examination are unclear. The values must be interpreted with caution, however. There is great interindividual and intraindividual variation in baseline cholinesterase values. A patient may have a 50% depression in cholinesterase activity, yet the level still falls within the “normal” reference range. This makes cholinesterase measurements of limited value in the initial diagnosis of
Additionally, adequate decontamination of the patient by removal of wet clothing and washing of contaminated skin with soap and water. ED personnel should wear gowns, gloves, and masks to prevent exposure to contaminated body fluids.3

As the patient is being decontaminated, the emergency physician (EP) should focus on the ABCs (airway, breathing circulation), with particular attention paid to early airway management for copious secretions, seizures, coma, severe weakness, and paralysis. If intubation is necessary, only a nondepolarizing neuromuscular blocking agent, such as vecuronium or rocuronium, should be used. Succinylcholine is metabolized by plasma cholinesterase, so prolonged paralysis may result if this agent is used a patient with OP poisoning.9

Treatment should next be directed at controlling muscarinic activity. Atropine is the drug of choice and should be administered intravenously at a dose of 2 to 5 mg (pediatric dose, 0.05 mg/kg) every 3 to 5 minutes, with the end point being control of respiratory secretions. Tachycardia is not a contraindication to atropine administration. Mild poisonings may resolve with just 1 to 2 mg of atropine, and severe poisonings may require more than 1000 mg.10 Large doses of atropine may lead to antimuscarinic CNS toxicity. If such toxicity occurs, glycopyrrolate (1 to 2 mg; pediatric dose, 0.025 mg/kg) can be used in place of atropine.

Pralidoxime is the antidote for OP insecticide poisoning. Although its efficacy may vary according to the structure of the OP compound, it should be given to all OP-poisoned patients. It works by increasing the rate of AChE regeneration. It is a common belief that pralidoxime is not beneficial if given after 24 hours because of the “aging” of AChE. However, OP insecticides have been detected in blood weeks after exposure, so pralidoxime therapy may still be of benefit. The adult dose is 1 to 2 g via the intravenous (IV) route delivered over a 15- to 30-minute period followed by a continuous infusion of 500 mg/hr. Pediatric dosing consists of a 25- to 50-mg/kg load followed by a 10- to 20-mg/kg/hr infusion. Pralidoxime is not indicated for carbamate poisoning, which is usually mild and self-limited.

**ORGANOCHLORINES**

**EPIDEMIOLOGY**

Organochlorines are heavily chlorinated aromatic compounds that are nonvolatile and poorly water soluble. They are

CHAPTER 146

Insecticides, Herbicides, and Rodenticides

Fig. 146.1 Treatment algorithm for organophosphorus insecticide poisoning. ABCs, Airway, breathing, and circulation; ABG, arterial blood gas determination; CBC, complete blood count; CXR, chest radiograph; ECG, electrocardiography; ICU, intensive care unit; IV, intravenous; RBC, red blood cell.

Organophosphate exposure

Inhalation

1. Remove and bag clothing
2. Assess ABCs

Establish IV access and intubate if necessary (DO NOT use succinylcholine, only nondepolarizing agents). Laboratory tests (RBC and plasma cholinesterase level, CBC, chemistry panel, liver profile, ABG), ECG, CXR. Treatment takes priority over evaluation

Excessive airway secretions?

Yes

1. Atropine, 2-5 mg IV (children: 0.05 mg/kg) even if tachycardic
2. Pralidoxime, 1-2 g over 30 min, then 500-mg/hr infusion (children: 25-50 mg/kg, then 10-20 mg/kg/hr). DO NOT give for carbamate poisoning

Do pulmonary symptoms resolve?

No

Repeat atropine dose; switch to glycopyrrolate, 1-2 mg (children: 0.02 mg/kg) for delirium or agitation from large doses of atropine

Yes

Admit to ICU

Ingestion

1. Remove and bag clothing
2. Assess ABCs

Wash skin with soap and water; irrigate eyes if exposed

Dermal

1. Remove and bag clothing
2. Assess ABCs

Establish IV access and intubate if necessary (DO NOT use succinylcholine, only nondepolarizing agents). Laboratory tests (RBC and plasma cholinesterase level, CBC, chemistry panel, liver profile, ABG), ECG, CXR. Treatment takes priority over evaluation

Excessive airway secretions?

Yes

1. Atropine, 2-5 mg IV (children: 0.05 mg/kg) even if tachycardic
2. Pralidoxime, 1-2 g over 30 min, then 500-mg/hr infusion (children: 25-50 mg/kg, then 10-20 mg/kg/hr). DO NOT give for carbamate poisoning

Do pulmonary symptoms resolve?

No

Repeat atropine dose; switch to glycopyrrolate, 1-2 mg (children: 0.02 mg/kg) for delirium or agitation from large doses of atropine

Yes

Admit to ICU

No

Inhalation Ingestion Dermal

Wash skin with soap and water; irrigate eyes if exposed

divided into four classes on the basis of their structural characteristics, and they vary tremendously with respect to dermal absorption, lipid solubility, and toxic doses. The clinical toxicity, which is similar for each of the classes, is summarized in (Table 146.3).

</table>
Most organochlorines have been banned in North America because of concern about their environmental persistence and bioconcentration. The only organochlorine still in common use in the United States is lindane (Kwell). It is used in agriculture as a seed treatment and medicinally as a topical scabicide in a 1% formulation. Toxicity from therapeutic lindane application is exceedingly rare, and most clinically relevant toxicity events occur as a result of inappropriate dermal application or ingestion.\textsuperscript{11-13}

**PATHOPHYSIOLOGY**

Lindane acts as an antagonist of γ-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the CNS.\textsuperscript{14} Toxicity results from loss of inhibitory tone and subsequent CNS hyperexcitability.

**PRESENTING SIGNS AND SYMPTOMS**

Symptoms, which can occur within 30 minutes of the ingestion of lindane,\textsuperscript{12} often include nausea and vomiting. With excessive or repeated topical applications, the onset of symptoms may be delayed from a few hours up to 4 to 5 days.\textsuperscript{11,14} CNS excitation is the hallmark of lindane toxicity. It is manifested by paresthesias, agitation, tremor, myoclonus, hallucinations, and most important, seizures. Seizures may occur suddenly and without prodrome. Complications of prolonged seizures may develop, including respiratory failure, metabolic acidosis, rhabdomyolysis, and hyperthermia.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis for suspected lindane poisoning is extremely broad because it can potentially include any cause of seizures. Appropriate, therapeutic use of lindane is not expected to produce toxicity. Unless a patient has ingested lindane before the onset of symptoms, an alternative explanation should be sought to explain the seizures. Although some laboratories can measure lindane levels, the results will not be immediately available to the EP. Therefore, the diagnosis is primarily clinical.

**TREATMENT**

No specific antidote is available for lindane toxicity. Although activated charcoal can be considered early after ingestion, it may be dangerous in a patient who may have seizures without warning. The mainstay of treatment is supportive. Benzodiazepines should be used to treat seizures. If that therapy is unsuccessful, barbiturates (phenobarbital) should be administered. As with other toxin-induced seizures, phenytoin is not indicated.

All symptomatic patients with lindane toxicity should be admitted to the hospital. Asymptomatic patients seen after the ingestion of lindane may be observed for 6 hours from the time of ingestion; if no symptoms develop, the patient can be medically cleared.

**PYRETHRINS AND PYRETHROIDS**

**EPIDEMIOLOGY**

Pyrethrins are naturally occurring esters of chrysanthemum resin that possess insecticidal activity, whereas pyrethroids are synthetic derivatives of pyrethrins. Exposures to these agents are commonly reported to poison centers. Most are accidental, and serious clinical effects are rare.\textsuperscript{7}

**PATHOPHYSIOLOGY**

Pyrethrins and pyrethroids delay closure of sodium channels. The delay results in prolonged depolarization, repetitive firing, and eventually conduction blockade.\textsuperscript{15} Some pyrethroids may inhibit GABA chloride channels, but it is unlikely that such inhibition plays a significant role in toxicity.

**PRESENTING SIGNS AND SYMPTOMS**

Most cases of clinically relevant toxicity from pyrethrins result from pulmonary allergic reactions rather than from direct toxic effects. The signs and symptoms are similar to those of asthma exacerbations and consist of wheezing, cough, dyspnea, and chest pain. Most reactions are mild and easily treated. However, fatal status asthmaticus has been reported with exposure to pyrethrin-containing shampoo.\textsuperscript{16,17}

Accidental or occupational exposure to pyrethroids usually produces minimal, if any, toxicity. The most common symptoms reported are facial paresthesias, dizziness, headache, nausea, anorexia, and fatigue.\textsuperscript{18} Massive exposures or large intentional ingestions may lead to more serious manifestations: seizures, altered mental status, coma, respiratory failure, and death.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis for pyrethrin and pyrethroid poisoning includes any other cause of allergic or asthmatic symptoms in most cases, but because treatment is the same, it is not important to know whether the exposure caused the symptoms. If the symptoms are neurologic or gastrointestinal, the differential diagnosis is quite broad; unfortunately, no laboratory or other test will help in differentiation.

**TREATMENT**

Activated charcoal may be given to a patient initially seen within 1 hour of a large oral ingestion of pyrethrin or pyrethroid. Skin decontamination is accomplished with soap and water. Pyrethrin-induced bronchospasm is treated with oxygen, β-adrenergic agonists, and corticosteroids as needed. No specific antidote is available, and the symptoms resolve with supportive care.
FIPRONIL

EPIDEMIOLOGY

Fipronil is a relatively new insecticide that was first introduced in 1996, and over the past several years it has increasingly been used to control common household insects, in addition to being used in flea and tick treatment for pets. Until recently, limited human toxicity data existed. It is commonly found in Frontline and Maxforce products.

PATHOPHYSIOLOGY

Fipronil acts as a GABA antagonist, which leads to excessive CNS excitation and death of the insect. It is more specific for the insect GABA receptor than it is for its mammalian counterpart.

PRESENTING SIGNS AND SYMPTOMS

The majority of human exposures are unintentional and most commonly result in neurologic symptoms such as dizziness and headache. Ocular and upper respiratory irritation has been reported commonly in addition to nausea and vomiting. More severe exposures or large intentional ingestions can cause CNS excitation and seizures.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Again, depending on the neurologic or gastrointestinal symptoms, the differential diagnosis may be broad and cannot be narrowed with any laboratory or diagnostic test. A history of exposure or potential exposure remains the most important key.

TREATMENT

Treatment of fipronil exposure remains primarily supportive and symptomatic. In patients with significant exposure who arrive at the ED in a state of CNS excitation or with seizures, the mainstay of treatment is airway protection and liberal use of benzodiazepines for sedation and control of the seizures.

Insecticides

Use glycopyrrolate in patients who need more atropine but show signs of central nervous system antimuscarinic toxicity, such as delirium and agitation. Do not rely on the pupils to rule in or rule out the diagnosis. The presence of tachycardia should not prevent administration of atropine to a patient with bronchorrhea or wheezing. Base treatment on clinical signs and symptoms, not on acetylcholinesterase levels.

RED FLAGS

Insecticides

Miosis in the setting of cholinergic symptoms, though not consistently present, is fairly specific for organophosphates and carbamate insecticides and may help make the diagnosis. Although the parasympathetic muscarinic effects are most often emphasized, certain sympathetic effects may predominate (sinus tachycardia is more common than bradycardia, and mydriasis may be seen). Nicotinic effects often predominate in mild cases and occur early in severe cases. “Normal” cholinesterase levels do not necessarily rule out poisoning if the history and clinical picture are otherwise indicative. Symptoms can occur within 30 minutes of the ingestion of lindane, but with excessive or repeated topical applications, the onset of symptoms may be delayed from a few hours to 4 to 5 days.

PARAQUAT AND DIQUAT

EPIDEMIOLOGY

Paraquat and diquat belong to the bipyridyl class of herbicides. They are both commonly used worldwide for weed control in the agricultural, horticultural, and forestry industries, and paraquat is marketed in more than 130 countries. Both compounds are available for home and commercial use in varying concentrations. Paraquat is commonly sold as a 0.2% solution for home use but can be found in 10% to 24% concentrated commercial solutions.

Paraquat and diquat account for only 4.9% of herbicide poisonings but are responsible for more than 50% of herbicide-related deaths. This fact points to the extremely toxic nature of these compounds. Most serious toxicity events and deaths are secondary to intentional ingestion.

PATHOPHYSIOLOGY

Paraquat is rapidly absorbed after ingestion and is concentrated in type I and type II alveolar epithelial cells. It is subsequently reduced to a free radical, which then reacts with oxygen to form a superoxide anion (O₂⁻). This anion then may form H₂O₂, which in the presence of Fe²⁺, will generate highly reactive hydroxyl radicals (•OH), which can cause oxidative damage to cells.
reactive species such as the hydroxyl radical (OH). These reactive molecules cause lipid peroxidation and cellular destruction.\textsuperscript{22} Initially, acute alveolitis may occur. Later, proliferative changes and pulmonary fibrosis are seen. Although paraquat concentrates mostly in the lungs, it is also distributed throughout the entire body and causes cellular destruction in multiple organs.

The pathophysiologic mechanism of diquat is similar to that of paraquat. Diquat does not concentrate in the lungs, however, and does not produce pulmonary fibrosis.\textsuperscript{23}

**PRESENTING SIGNS AND SYMPTOMS**

Paraquat poisoning can be classified as mild, moderate, or severe according to the amount ingested.\textsuperscript{21} Physical examination findings are summarized in Table 146.4. Mild poisonings, which occur when small amounts of dilute preparations are ingested, are characterized by the development of gastrointestinal symptoms without other organ toxicity. As the amount of paraquat or diquat ion ingested rises, worsening gastrointestinal effects are seen, including severe oropharyngeal, esophageal, and gastric ulceration. Large ingestions produce renal and hepatic failure within a few days. Paraquat toxicity results in pulmonary fibrosis and refractory hypoxemia several days to weeks after ingestion, and death usually occurs within a few weeks. Massive ingestions cause multiorgan failure and death within a few days. Diquat toxicity does not produce pulmonary fibrosis. Diquat ingestion has been associated with brainstem infarction.\textsuperscript{23} Effects from dermal exposure to paraquat and diquat are usually mild, but ulcers and blistering can occur with highly concentrated formulations.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

A qualitative urine test can be performed to aid in the diagnosis of paraquat or diquat poisoning. When alkaline sodium dithionate is added to urine, the color turns blue when paraquat is present and blue-green in the presence of diquat. Quantitative plasma measurements may also be obtained to confirm exposure and determine prognosis. Neither of these tests may be readily available in the emergency setting. Therefore, the diagnosis is often based on the history alone. The differential diagnosis of paraquat and diquat poisoning is wide and includes exposure to other caustic substances.

**TREATMENT**

No specific antidote or pharmacologic intervention has been proven to affect outcome after paraquat or diquat poisoning. Early decontamination is the most important step in initial management and may be futile after large ingestions because of rapid absorption. There is little clinical or experimental evidence for the use of gastric lavage, and the procedure may even worsen the oral or esophageal ulceration. Therefore, activated charcoal (1 to 2 g/kg) is the agent of choice for gastric decontamination. Other agents, such as diatomaceous fuller’s earth (1 to 2 g/kg in a 30% aqueous solution) and bentonite (1 to 2 g/kg of a 7% aqueous solution), have been used but are not as likely to be available to the EP, nor do they provide any advantage over charcoal. Gastric decontamination should be initiated as soon as possible.

Supportive care should be provided, with airway protection and ventilation being paramount. Supplemental oxygen may worsen the toxicity by accelerating the damage caused by oxygen radicals. It is generally accepted that supplemental oxygen be withheld until the PaO\textsubscript{2} value falls below 40 to 50 mm Hg. IV fluids should be given to ensure normal urine output and analgesics provided for the pain associated with mucosal ulcerations. Many other pharmacologic treatments of paraquat poisoning have been investigated, but none have proved useful.\textsuperscript{22} Hemoperfusion and hemodialysis are effective in removing paraquat from the blood, but neither improves the prognosis.

**CHLORPHENOXY HERBICIDES**

**EPIDEMIOLOGY**

Chlorphenoxy herbicides are widely used to control the growth of broad-leaved weeds in pastures and crop fields and

</table>
along public streets. Poisoning is uncommon, and most ED encounters consist of accidental dermal or inhalational exposure, for which serious systemic toxicity is rare. However, intentional ingestion of these compounds carries high morbidity and mortality. From 1962 to 2004, 69 cases of ingestion of chlorophenoxy herbicides alone (excluding other pesticides as coingestants) were reported. One third of the patients in these reports died.24

**PATHOPHYSIOLOGY**

The pathophysiology of chlorphenoxy herbicide toxicity involves three mechanisms. First, a dose-dependent disruption of cell membranes is thought to be responsible for mediation of CNS toxicity through disruption of the blood-brain barrier. Second, these compounds may form analogues of acetyl coenzyme A (CoA) and thereby disrupt its role in cellular metabolism. Because acetyl CoA is involved in formation of the neurotransmitter ACh, false cholinergic transmitters may be formed. A third mechanism of toxicity results from uncoupling of oxidative phosphorylation, which leads to depletion of cellular adenosine triphosphate.25

**PRESENTING SIGNS AND SYMPTOMS**

Vomiting is common early after ingestion and may be accompanied by abdominal pain and diarrhea. Hypotension may occur secondary to volume loss, peripheral vasodilation, and direct myocardial toxicity. Severe ingestions are often associated with a rapid onset of coma. Other neurologic features that have been reported are hyperreflexia, hypertonia, seizures, hallucinations, clonus, and ataxia.24,25 Peripheral neuromuscular effects include weakness, loss of deep tendon reflexes, and fasciculations. Common metabolic effects are acidosis, hyperthermia, and rhabdomyolysis.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The diagnosis is made by obtaining a history of ingestion of or exposure to these agents. Plasma levels can be measured, but the results are not available in the emergency setting. When the history is lacking, the diagnosis is difficult to make because the differential diagnosis includes any potential cause of metabolic acidosis, myopathy, changes in mental status, and gastroenteritis.

**TREATMENT**

Most patients can be managed with supportive care alone. Activated charcoal should be given if the patient is seen within 1 hour of a large ingestion. Other supportive measures are airway protection, IV fluids, and benzodiazepines for seizures, fasciculations, hyperreflexia, or clonus. Alkaline diuresis has been reported to reduce the half-life of 2,4-dichlorophenoxyacetic acid (2,4-D).26 Although hemodialysis and resin hemoperfusion enhance elimination of 2,4-D, no controlled trials have been conducted to assess whether these measures change the outcome. These modalities should be considered only for severe poisonings.

**GLYPHOSATE**

Glyphosate is a widely used herbicide with formulations that range from a 1% household concentration to a 41% concentrate for commercial use. In addition, many of the commercial formulations are mixed with surfactants, which themselves produce toxicity by destroying mitochondrial cell walls and interfering with cellular energy production. The amine surfactants are also highly alkaline and corrosive and thus contribute to much of the toxicity of glyphosate.

Unintentional or small ingestions of glyphosate typically produce only mild gastrointestinal symptoms. An exception occurs with glyphosate-trimesium (Touchdown), which has produced rapid death after small ingestions.27 Most cases of significant toxicity result from intentional ingestion of the concentrated formulation of Roundup (41% glyphosate and 15% polyoxyethyleneamine surfactant). Common features are corrosive effects, such as oropharyngeal ulcers, dysphagia, abdominal pain, and vomiting. Significant laryngeal injury may lead to aspiration and lung injury. Metabolic acidosis is common with large ingestions of concentrated formulations. Hypovolemia and hypoperfusion may lead to secondary hepatic and renal insufficiency.28

**Glufosinate**

Glufosinate is a nonselective herbicide used worldwide and marketed under the trade names BASTA, Ignite, Challenge, and Harvest. A glutamic acid analogue, glufosinate is combined with surfactants. As with glyphosate, ingestion of these products can lead to symptoms attributable to surfactants, such as corrosive injury, gastrointestinal symptoms, and acidosis. However, glufosinate is unique in that it may cause delayed onset of CNS toxicity. Ataxia, depressed level of consciousness, coma, and central apnea may develop 4 to 12
Rodenticides vary greatly with respect to pathophysiology, signs and symptoms, degree of toxicity, and management. Because these poisonings are rarely encountered by EPs, a detailed discussion on each one is beyond the scope of this text. Some of the characteristics can be found in Table 146.5. Instead, attention is directed to the anticoagulant rodenticides warfarin and superwarfarin and the compound strychnine, which can be found in some rodenticides today.

**Rodenticides**

Ingestion of an anticoagulant rodenticide should be considered when a patient has an elevated prothrombin time or bleeding without other explanation. The differential diagnosis includes vitamin K deficiency, hemophilia or other factor deficiencies, and disseminated intravascular coagulation. The myriad causes of liver failure must also be considered, including viral hepatitis, alcoholic cirrhosis, hepatotoxic ingestions (e.g., acetaminophen, iron), and Wilson disease. A thorough laboratory evaluation aimed at sorting out these processes should be obtained, including a complete blood count, prothrombin and partial thromboplastin times, international normalized ratio, liver enzymes, fibrinogen and fibrin split products, measurements of coagulation factors (II, VII, IX, X), and a 50:50 mixing test. Brodifacoum and difenacoum measurements may be performed, but their results will not be immediately available to the EP.

**PRESENTING SIGNS AND SYMPTOMS**

When a child is evaluated immediately after an unintentional ingestion, the child will be asymptomatic without signs of bleeding; 24 to 48 hours after a large ingestion, however, the child may have any manifestation of a coagulopathy, including, in order of decreasing frequency, ecchymosis, hematuria, uterine bleeding, gastrointestinal bleeding, epistaxis, spontaneous hemoptysis, gingival bleeding, hemoptysis, and hematemesis.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Ingestion of an anticoagulant rodenticide should be considered when a patient has an elevated prothrombin time or bleeding without other explanation. The differential diagnosis includes vitamin K deficiency, hemophilia or other factor deficiencies, and disseminated intravascular coagulation. The myriad causes of liver failure must also be considered, including viral hepatitis, alcoholic cirrhosis, hepatotoxic ingestions (e.g., acetaminophen, iron), and Wilson disease. A thorough laboratory evaluation aimed at sorting out these processes should be obtained, including a complete blood count, prothrombin and partial thromboplastin times, international normalized ratio, liver enzymes, fibrinogen and fibrin split products, measurements of coagulation factors (II, VII, IX, X), and a 50:50 mixing test. Brodifacoum and difenacoum measurements may be performed, but their results will not be immediately available to the EP.

**TREATMENT**

Figure 146.2 summarizes the management of warfarin or superwarfarin poisoning, which depends on the timing, amount ingested, and symptomatology. Accidental ingestions of less than one box of 4-hydroxycoumarin are unlikely to result in clinically significant toxicity and may be managed without gastric decontamination or laboratory evaluation unless signs of bleeding occur. Patients who ingest one or more boxes should be given activated charcoal if they are seen within 1 hour of ingestion. Acute hemorrhage is managed with oxygen and IV crystalloids to replace losses of volume. Fresh frozen plasma should be administered to patients with active bleeding and coagulopathies. Vitamin K₁ is given at doses of 1 to 5 mg in children and 10 mg in adults. It may be administered intravenously at no more than 1 mg/min to reduce the likelihood of anaphylactoid reactions. Oral or subcutaneous administration is also acceptable.

CHAPTER 146 INSECTICIDES, HERBICIDES, AND RODENTICIDES

Fig. 146.2 Algorithm for the management of superwarfarin ingestions. CBC, Complete blood count; FFP, fresh frozen plasma; GI, gastrointestinal; ICU, intensive care unit; INR, international normalized ratio; IV, intravenous; PT, prothrombin time; PPT, partial thromboplastin time.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

All patients with signs and symptoms of bleeding should be admitted to the hospital for reversal of coagulopathy and control of bleeding. Those with severe or life-threatening hemorrhage warrant admission to the intensive care unit. Asymptomatic patients seen after ingestion can be discharged with arrangements to have blood specimens obtained for measurement of the prothrombin time on an outpatient basis in 24 and 48 hours.

**STRYCHNINE**

**EPIDEMIOLOGY**

Strychnine is a naturally occurring alkaloid derived from seeds of the tree *Strychnos nux-vomica*. Though rarely used as a rodenticide today, it is still available in some gopher, mouse, and rat poisons. It has also been found in certain traditional Cambodian home remedies. Strychnine is an odorless
crystalline white powder with a bitter taste that is well absorbed in the gastrointestinal tract.

**PATHOPHYSIOLOGY**

Strychnine blocks the postsynaptic binding of glycine in the spinal cord and brainstem. Because glycine is the major inhibitory neurotransmitter in these areas, disinhibition results in excessive stimulation of motor neurons.34

**PRESENTING SIGNS AND SYMPTOMS**

Symptoms usually begin within 15 to 30 minutes of ingestion. Initial symptoms include a heightened sense of awareness and muscle spasms. As the toxicity progresses, the muscular hyperexcitability worsens. Minimal stimuli can produce severe muscle spasms, opisthotonos, and trismus, which can be indistinguishable from seizures. Patients generally maintain a clear sensorium before and after these episodes, an effect unique to strychnine ingestion.34 The complications of strychnine poisoning are secondary to muscle spasms and include hyperthermia, metabolic acidosis, and rhabdomyolysis. Death is usually the result of respiratory failure from spasm of the respiratory muscles.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The diagnosis is based on a history of exposure in a patient with the aforementioned signs and symptoms. If the history is unknown, the differential diagnosis includes stimulant intoxication, alcohol or benzodiazepine withdrawal, neuroleptic malignant syndrome, serotonin syndrome, salicylate intoxication, encephalitis, meningitis, and tetanus.

**TREATMENT**

Treatment is largely supportive, with a focus on airway protection and management of muscle spasms with benzodiazepines. Activated charcoal is unlikely to be of benefit given the rapid absorption and onset of symptoms. For mild symptoms, the patient should be administered diazepam or lorazepam and placed in a dark quiet environment to avoid stimuli. Airway and ventilatory status must be monitored closely and continuously because sudden deterioration can occur. Patients with severe symptoms should be intubated and paralyzed with a nondepolarizing neuromuscular blocker. They should then be aggressively sedated with benzodiazepines, propofol, or barbiturates. If this approach fails to control the muscle activity, continuous neuromuscular paralysis is an option. All symptomatic patients should be admitted to the intensive care unit.

**REFERENCES**

References can be found on Expert Consult @ www.expertconsult.com.
REFERENCES

syndrome occur less often with atypical antipsychotics than with the typical agents.

**PATHOPHYSIOLOGY**

The prevailing theory of depression implicates an imbalance in various neurotransmitters and their receptors. Pharmacologic therapy has been engineered to neuromodulate these imbalances. Consequently, the signs and symptoms seen in a significant overdose of an antidepressant medication are the results of gross derangement of one or more neurotransmitters.

**TRICYCLIC ANTIDEPRESSANTS**

TCAs have similar ring structures and, with only a few exceptions, result in a related toxicity. Examples are amitriptyline (Elavil), imipramine (Tofranil), and doxepin (Sinequan). The five major pharmacologic effects of TCAs are listed in Table 147.1.

**MONOAMINE OXIDASE INHIBITORS**

Phenelzine (Nardil) and tranylcypromine (Parnate) are the two most commonly prescribed MAOIs in the United States, and they account for the majority of toxicity seen with this class of agents. The pharmacologic effects of MAOIs are listed in Box 147.1. These effects in overdose may result in a sympathomimetic toxidrome followed by profound hypotension. A therapeutic dose of an MAOI can interact with certain foods, drinks, and other pharmacologic agents and cause serious toxicity.

**SELECTIVE SEROTONIN REUPTAKE INHIBITORS**

Selective SRI antidepressants commonly prescribed are sertraline (Zoloft), paroxetine (Paxil), fluoxetine (Prozac), citalopram (Celexa), and escitalopram (Lexapro). The clinically beneficial central nervous system (CNS) effects of SRIs are thought to result from blockade of presynaptic reuptake of serotonin at 5-hydroxytryptamine type 1 (5-HT1) receptors. This blockade leads to higher synaptic serotonin levels and hence has positive effects on mood. Overdoses of these agents are much safer than overdoses of TCAs or MAOIs, although significant morbidity and mortality may occur with significant syndrome.

overdose or, more commonly, with ingestion of an SRI in combination with ingestion of agents possessing proserotonergic activity.

**ATYPICAL ANTIPSYCHOTICS**

The pharmacologic mechanism of action of atypical agents includes blockade at dopamine ($D_2$) receptors and serotonin (5-HT$_{2A}$) receptors. These agents can also cause repolarization abnormalities by blocking potassium efflux in the myocardium and thereby increasing the risk of torsades de pointes (Box 147.2).

**LITHIUM**

The lightest metal known, lithium is in the same group of elements as sodium and potassium and therefore has similar chemical properties. Since the early 1970s, lithium has been
The onset of action occurs within 8 hours, but the effects may not manifest until 24 hours and may last for several days. Agitation, delirium, seizures, coma, and muscular rigidity predominate. Late in the clinical course of a significant poisoning, depletion of catecholamines can result in asystole. In the presence of increased sympathetic tone, rhabdomyolysis may occur.

MAOI interactions with foods or beverages (aged cheeses, fava beans, ales, wines) produce early onset of signs and symptoms within minutes to hours. Because of tyramine’s short-lived action on the adrenal medulla (to increase endogenous amines), these interactions last only several hours. Interactions of MAOIs with other drugs (sympathomimetics, methylxanthines, SRIs, meperidine) also lead to elevated sympathetic tone. This effect manifests within minutes to hours and can last several hours to days.

SEROTONIN REUPTAKE INHIBITORS
Overdose of SRIs causes CNS abnormalities (sedation, agitation, delirium), peripheral alterations (tremor, hyperreflexia, rigidity), cardiovascular changes (tachycardia, bradycardia), nausea or vomiting, and lightheadedness. The patient with citalopram or escitalopram overdose should be observed for seizures and QTc and/or QRS interval lengthening. Although isolated SRI ingestions frequently result in only mild toxicity, severe overdose or concomitant ingestion of proserotonergic medications can lead to serotonin excess and serotonin syndrome (Fig. 147.3). A history of ingestion of serotonergic agents, altered mental status, autonomic instability, and peripheral signs of rigidity or hyperreflexia are usually present.

ATYPICAL ANTIPSYCHOTICS
Patients usually present within a few hours of atypical antipsychotic overdose with signs of CNS depression (sedation,
confusion, coma). Hypotension and reflex tachycardia from peripheral vasodilation may also occur. Miosis may lead the examiner to consider opioid poisoning. QTc prolongation can be seen in therapeutic use, as well as in overdose. Other adverse effects, which are less commonly seen with the newer agents, are acute dystonias, akathisia, and tardive dyskinesia.

The most significant extrapyramidal effect is neuroleptic malignant syndrome (NMS). NMS results when dopamine-blocking agents yield "dopamine-depleted" activity at D2 receptors in the CNS. Although NMS can occur after an intentional overdose, it usually arises after an increase in dose or after the addition of agents with similar activity (e.g., lithium inhibition of dopamine secretion). Manifestations of NMS include CNS abnormalities (sedation, agitation, delirium), peripheral alterations (tremor, hyperreflexia, rigidity), and cardiovascular changes with autonomic instability (tachycardia, bradycardia, hyperthermia) much like those seen in serotonin syndrome. Unlike serotonin syndrome, in which onset of symptoms is normally rather quick, NMS occurs insidiously. Historical information and medication lists are often required to differentiate between the two conditions (Table 147.2).

LITHIUM

The clinical effects of lithium overdose are gastrointestinal (nausea, vomiting, and diarrhea), neurologic (tremor, confusion, ataxia, weakness), and cardiovascular (QTc prolongation, bradycardia, T-wave flattening or inversion, bundle branch blocks). Adverse effects include nephrogenic diabetes insipidus, polyuria, psoriasis, alopecia, edema, and leukocytosis. Gastrointestinal distress is usually one of the first manifestations of lithium toxicity. Many presentations are chronic and result from continued lithium administration in the presence of dehydration (decreased fluid intake or vomiting and diarrhea). Physiologically, lithium cannot be differentiated from sodium and is retained by the kidney in patients with dehydration. The results are greater CNS levels and subsequent toxicity. Additionally, changes in a patient’s renal function may decrease lithium clearance.

  - Anticholinergics
  - Amphetamines
  - Cocaine
  - Lithium
  - Lysergic acid diethylamide (LSD)
  - Phencyclidine (PCP)
  - Salicylates
  - Water hemlock

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Any sedating agent (e.g., opioids, ethanol, benzodiazepines) should be considered in the differential diagnosis of most antidepressant and antipsychotic overdoses. Serotonin syndrome (e.g., SRIs, ecstasy, meperidine, lithium, dextromethorphan, L-tryptophan), neuroleptic malignant syndrome (e.g., antipsychotics such as phenothiazines), malignant hyperthermia (e.g., volatile anesthetic agent use), sympathomimetic overdrive (e.g., cocaine, amphetamines), and MAOI overdose or drug-food interaction should also be considered (Box 147.3).

**TRICYCLIC ANTIDEPRESSANTS**

The differential diagnosis of TCA overdose should be broader and should include anticholinergic and antihistamine products (e.g., diphenhydramine) and agents that can poison fast sodium channels, thereby lengthening the QRS interval (e.g., type I antidysrhythmics, cocaine, diphenhydramine, propoxyphene, carbamazepine, cyclobenzaprine, phenothiazines). Life-threatening features are hyperthermia associated with mental status changes, autonomic instability, and tremors, clonus, and rigidity. Life-threatening toxicity should be anticipated in an adult who has ingested TCA doses of 10 mg/kg or greater. Qualitative urine screens for TCAs are of no diagnostic benefit. Although quantitative serum levels of TCAs greater than 1000 ng/mL (therapeutic, 50 to 300 ng/mL) have been correlated with severe toxicity, quantitative testing may not be available in a timely fashion. In addition, depending on the time from ingestion, the type of TCA taken, and the chronicity of dosing, patients may be very ill with serum levels much lower than 1000 ng/mL. An electrocardiogram (ECG) is the diagnostic test of choice. Normal ECG findings do not fully exclude TCA poisoning, but QRS prolongation greater than 120 msec should be a threshold for treatment (Fig. 147.4). Cardiac monitoring helps discern the severity of
A study showed that the sensitivity of a QRS interval longer than 100 msec can be matched by two other parameters: the terminal 40 msec of lead aVR measuring longer than 3 mm (R wave in aVR > 3 mm), and a ratio of R-wave to S-wave amplitude in the aVR lead greater than 0.7 (Fig. 147.5).

Toxicity. Maximal limb-lead QRS interval duration is a sensitive indicator of illness. Generally, QRS intervals longer than 100 msec are associated with a 33% incidence of seizure activity, and QRS intervals longer than 160 msec are associated with a 50% incidence of ventricular dysrhythmia. One study showed that the sensitivity of a QRS interval longer than 100 msec can be matched by two other parameters: the terminal 40 msec of lead aVR measuring longer than 3 mm (R wave in aVR > 3 mm), and a ratio of R-wave to S-wave amplitude in the aVR lead greater than 0.7 (Fig. 147.5).
MONOAMINE OXIDASE INHIBITORS
A clinical diagnosis (largely based on historical facts) is required for MAOI overdose. No laboratory (urine or blood) test is readily available to make a diagnosis of MAOI poisoning.

SEROTONIN REUPTAKE INHIBITORS
The diagnosis of SRI toxicity is purely clinical. The criteria for serotonin syndrome are met through focused elicitation of historical information and the finding of signs and symptoms consistent with the disorder (Table 147.3).16

ATYPICAL ANTIPSYCHOTICS
Blood or urine testing plays no role in the diagnosis of atypical antipsychotic overdose. Although QTc prolongation can occur after both therapeutic and toxic ingestions, this finding is not specific for these agents. NMS is a clinical diagnosis coupled with diligent history taking.

LITHIUM
Clinical suspicion, historical features, and serum lithium concentrations form the basis of the diagnosis of lithium poisoning. Serum concentrations must be interpreted in the context of chronicity and timing of ingestion. Because long-term users of this drug have higher CNS levels, ill effects occur at lower serum levels. Additionally, lithium has a long distribution time after absorption. In light of this feature, measurement of a serum lithium level less than 6 hours after the last dose may yield an excessively elevated concentration (therapeutic, 0.6 to 1.2 ng/mL). Generally, serum lithium levels greater than 4 ng/mL in acute ingestion and greater than 2.5 ng/mL in chronic poisoning are considered significant.

TREATMENT
TRICYCLIC ANTIDEPRESSANTS
The treatment of TCA overdose depends on symptoms and is most effectively judged from the ECG (Fig. 147.6). Decontamination is best done early after the overdose. Gastric lavage can be considered after life-threatening ingestion and early presentation (<1 hour). The mainstay of decontamination is activated charcoal. The risks of each technique should be weighed against the potential benefits. Unruly behavior, seizure activity, decreased mental status, and loss of airway reflexes are poor predictors of success and thus raise the risk of aspiration.

Focused therapy consists of serum alkalinization with intravenous sodium bicarbonate (NaHCO3). Administration of boluses of 1 to 2 mEq/kg is accompanied by close examination of the QRS interval. Boluses should be repeated every 5 minutes until QRS widening resolves, dysrhythmias occur, or blood pH exceeds 7.55. Rarely, hypertonic saline solution can be considered for prolonged QRS intervals and severe alkalemia. NaHCO3 drips—3 ampules added to 1 L of 5% dextrose in water (D5W) and given at rates of 2 to 3 mL/kg/hour—and hyperventilation with ventilatory support are considered adjuncts to NaHCO3 bolus therapy. Serum potassium levels should be monitored with this therapy, and potassium losses should be replaced as necessary.

Seizure activity should be managed with sedatives such as benzodiazepines and barbiturates. If muscle paralysis is necessary, continuous electroencephalographic techniques should be used to measure occult seizure activity. Lidocaine is an alternative to NaHCO3 therapy for dysrhythmias. Class IA, IC, and III antidysrhythmics, beta-antagonists, and calcium channel blockers are contraindicated in the patient with TCA overdose. Flumazenil and physostigmine are also poor treatment strategies because they have been reported to cause seizure activity and asystolic arrest, respectively.

MONOAMINE OXIDASE INHIBITORS
Decontamination techniques in patients with MAOI overdoses should include activated charcoal and, possibly, gastric lavage for significant ingestions without contraindication. No specific antidote is effective. Supportive care should be provided for hemodynamic compromise and/or hyperthermia. Beta-blockers and calcium channel blockers for treatment of tachycardia or hypertension should be avoided because of the theoretical concern of unopposed peripheral α1-adrenergic vasoconstriction and worsening hypertension or the development of hypotension and bradycardia, respectively. Rather, phentolamine (bolus of 5 mg in adults and 0.02 mg/kg to 0.1 mg/kg in children, repeated in 5 to 10 minutes as needed) or nitroprusside (0.3 mcg/kg/minute titrated to effect) should be considered for hypertensive emergencies. Ventricular

| Hunter’s criteria for serotonin toxicity (context of serotonergic medications) | 1. If patient has spontaneous clonus, serotonin toxicity present |
| | 2. If no spontaneous clonus, one of the following needed for a diagnosis of serotonin toxicity: |
| | • Inducible clonus and agitation or diaphoresis |
| | • Ocular clonus and agitation or diaphoresis |
| | • Tremor and hyperreflexia |
| | • Temperature > 38°C and ocular clonus or inducible clonus |
Standard activated charcoal decontamination should be employed for SRI overdose. Supportive care of the airway, breathing, and circulation encompasses the majority of treatment. In cases of serotonin syndrome, aggressive cooling measures for hyperthermia, benzodiazepines for agitation, and intravenous fluids are usually the only interventions.
required to decrease the risk of death. Life-threatening hyperthermia should be treated with sedation, neuromuscular paralysis, and ventilatory care. The use of cyproheptadine (8 mg by mouth; up to 24 mg per day) for serotonin syndrome has been described but remains controversial. Bromocriptine has been reported to worsen serotonin syndrome, and dantrolene (proven effective for malignant hyperthermia) should be considered only for life-threatening hyperthermia and significant rigidity.

**ATYPICAL ANTIPSYCHOTICS**

Acute overdose of atypical antipsychotic agents is managed with supportive care because no specific antidote exists. These agents bind to activated charcoal, use of which should be the standard mode of decontamination. Correction of electrolyte (potassium, magnesium, and calcium) disturbances helps prevent widening or further lengthening of the QTc interval. The prophylactic use of magnesium to prevent a widened QTc interval from degenerating into torsades de pointes has no proven benefit when magnesium concentrations are normal. Treatment of NMS is for the most part identical to that of serotonin syndrome (aggressive cooling, benzodiazepines for agitation, fluids, and ventilatory support as warranted). Bromocriptine, an antihistamine with dopaminergic agonist activity, has been used without consistent benefit. Dantrolene, which works peripherally to inhibit release of calcium from the sarcoplasmic reticulum, has never been proven to be of benefit in NMS but should be considered for the patient with significant rigidity and life-threatening hyperthermia.19

**LITHIUM**

Treatment of lithium poisoning depends on the clinical context. Activated charcoal is contraindicated because lithium does not bind to it, and whole-bowel irrigation is considered only with ingestions of sustained-release products in patients with no contraindications. Sodium polystyrene sulfonate has been shown to bind to lithium in vitro, but in clinical use it requires excessive dosing at the risk of potentially causing hypokalemia.

Enhancing elimination through hemodialysis is a controversial topic in the setting of lithium poisoning. The patient likely to benefit is the one with acute ingestion, mental status abnormalities, and/or significant renal dysfunction or pulmonary edema. Many patients experience lithium “redistribution” and an asymptomatic period after hemodialysis. This result often leads to further hemodialysis sessions, but whether this approach has an ultimate beneficial outcome remains controversial. The more common approach, barring any of the preceding abnormalities, is fluid hydration. Lithium’s clearance depends on the glomerular filtration rate, which, in turn, depends on volume status. Dehydrated patients continue to reabsorb, rather than eliminate, lithium because of its physical characteristics. Crystalloids given at two times maintenance doses should suffice. Forced diuresis or diuretic therapy has no role in this situation.

Table 147.4 summarizes treatment of overdoses involving antidepressant and antipsychotic agents other than TCAs.

*IV, Intravenous.*

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Any patient with a deliberate overdose of an antidepressant or antipsychotic medication or with clinical symptoms should be admitted to the hospital. Patients who are asymptomatic 6 hours after ingestion can be medically cleared for psychiatric evaluation. The exceptions are patients with elevated serum lithium values, who warrant further observation and subsequent lithium measurements, and patients with overdose of an
MAOI agent, which may not manifest for 24 hours. Patients should be admitted to the intensive care unit for any mental status changes that require close observation for loss of airway reflexes or seizure activity. In addition, patients with cardiovascular abnormalities, especially those requiring treatment in the emergency department with NaHCO₃, lidocaine, or other cardiovascular drugs, merit disposition to a critical care unit.

**TIPS AND TRICKS**

- Although normal electrocardiographic findings do not fully exclude tricyclic antidepressant (TCA) poisoning, QRS prolongation to more than 100 to 120 msec should be a threshold for treatment.
- Generally, QRS duration longer than 100 msec is associated with a 33% incidence of seizure activity, and a QRS greater than 160 msec is associated with a 50% incidence of ventricular dysrhythmia. Cardiac monitoring is a valid way of discerning the severity of toxicity in TCA poisoning.
- Devastating hemodynamic instability follows seizure activity in 13% of patients with TCA poisoning.
- Rightward deviation of the terminal 40-msec QRS axis (R wave in aVR > 3 mm) should be a cause for concern in a patient with TCA overdose.
- Significant, late monoamine oxidase inhibitor poisoning results in asystole from depletion of catecholamines, so affected patients should be monitored for 24 hours.
- Atypical antipsychotic toxicity can be associated with sedation or coma and miosis and therefore can be confused with opiate intoxication.
- Lithium toxicity is often precipitated by dehydration or worsening renal function.
- A serum lithium value obtained less than 6 hours after the last dose may result in excessively elevated concentrations (therapeutic, 0.6-1.2 ng/mL).

Cardiovascular Drugs
Kirk L. Cumpston

KEY POINTS

- Cardiovascular drugs are responsible for many fatalities.
- β-Receptor antagonists, calcium channel antagonists, and digoxin primarily cause toxicity by disruption of intracellular calcium homeostasis and lead to hypotension and dysrhythmias.
- With sustained-release forms of calcium channel antagonists and β-receptor antagonists, toxicity has a delayed peak and longer duration, which can lead to cardiovascular collapse and arrest if treatment is delayed or there is insufficient cardiovascular monitoring.
- Diagnostic testing should include continuous cardiac monitoring; electrocardiogram; measurement of appropriate serum drug concentrations, electrolytes, and glucose; and investigation of coingestants.
- The call to the pharmacist to obtain the hyperinsulinemia-euglycemia infusion in calcium channel antagonist overdose should be made when the norepinephrine infusion is begun.

EPIDEMIOLOGY

The pervasiveness of hypertension, congestive heart failure, and coronary artery disease in the United States has led to an immense number of prescriptions for β-receptor antagonists and calcium channel antagonists. The prevalence of digoxin as a therapy for atrial fibrillation and congestive heart failure has ostensibly diminished, but it is still prescribed.

The 2009 Annual Report of the American Association of Poison Control Centers National Poison Center Database System reported cardiovascular drugs as the second most common cause of fatalities overall (10%), and they were the second fastest in rate of exposure increase.1 Cardiovascular drugs as a category were ranked as the fifth leading cause of death (44 total deaths: 5 from β-receptor antagonists, 16 from calcium channel antagonists, and 23 from cardiac glycosides). These specific cardiovascular drugs share the clinical effects of hypotension, bradycardia, and conduction disturbances. However, unique differences can help distinguish them in an unknown overdose (Fig. 148.1). Other pharmacological included in the category of cardiovascular agents are angiotensin-converting enzyme inhibitors, antiarrhythmics, clonidine, and other antihypertensives; they are not discussed in this chapter.

CALCIUM CHANNEL ANTAGONISTS

PATHOPHYSIOLOGY

Calcium channel antagonists block the intracellular flow of calcium ions through L-type voltage-gated calcium channels in myocardial, smooth muscle, and pancreatic beta-islet cells. These mechanisms of action result in cardiovascular toxicity both directly and indirectly. Depending on the selectivity of the calcium channel antagonist, the direct cardiovascular toxicity is a combination of the effects on the cardiac conduction system, myocardial contractility, and vascular smooth muscle vasodilation. The dihydropyridine class (e.g., amlodipine, nifedipine) preferentially acts on the peripheral vasculature, thereby potentially leading to hypotension and reflex tachycardia. Verapamil operates on the sinoatrial and atrioventricular (AV) nodes and on the myocardium. Diltiazem acts to a lesser extent than verapamil on the cardiac tissue and nodes, and it also dilates peripheral vasculature (Table 148.1). The degree of contribution from each mechanism of cardiovascular toxicity can be difficult to predict. Despite the differences in therapeutic mechanisms, the distinctions among families of calcium channel antagonists are often blurred during an overdose, and the patient generally suffers from negative chronotropic, inotropic, and dromotropic effects.2

Calcium channel antagonist overdose also results in indirect toxicity from attenuation of the release of insulin from the pancreatic beta-islet cells. This inhibition leads to hyperglycemia and intracellular catabolism of fatty acids to create energy. The hypoinsulinemia contributes to impairment of cardiac function and shock by preventing the use of glucose as a metabolic substrate. Negative inotropy and diminished peripheral vascular resistance lead to shock and subsequently to metabolic acidosis; the result is a laboratory picture similar to that of diabetic ketoacidosis.

PRESENTING SIGNS AND SYMPTOMS

Because the calcium channel antagonists were developed to affect the cardiovascular system, the presenting signs and symptoms of overdose with such agents are primarily related to a malfunction of this system. Hypotension is the hallmark of calcium channel antagonist toxicity.

Reflexive tachycardia can occur as a result of peripheral vasodilation after an overdose of a calcium channel antagonist in the dihydropyridine class, but this effect may be transient, and bradycardia usually develops in large overdoses. This
tachycardia may prove fortunate in maintaining organ perfusion by sustaining cardiac output when the stroke volume is depleted.

Verapamil and diltiazem overdoses cause bradycardia and numerous conduction abnormalities in and below the AV node. The decreased blood pressure results from vasodilation and decreased cardiac contractility from the negative inotropic and chronotropic effects.3

Patients often complain of chest pain, dyspnea, dizziness, syncope, and palpitations. Other clinical manifestations are confusion, agitation, seizures, pulmonary edema (cardiogenic and noncardiogenic), hyperglycemia, and metabolic acidosis.

The differential diagnosis (see also Fig. 148.1) for overdose of calcium channel antagonists includes other cardiovascular drugs such as beta-blockers, clonidine, digitalis, and other antidysrhythmics. The emergency physician should also consider myocardial infarction and other causes of cardiogenic shock. The potency of the effect of calcium channel antagonists on the cardiovascular system is astounding. Significant cardiovascular toxicity can occur after supratherapeutic ingestion of calcium channel antagonists. Ingestion of double the therapeutic dose should instigate medical evaluation and...
treatment. Immediate-release calcium channel antagonists should have some clinical effect within 6 hours. Sustained-release calcium channel antagonists should result in clinical manifestations within 1 to 14 hours.5

Nearly all calcium channel antagonists are manufactured in modified-release formulation. This is convenient therapeutic dosing for the patient, but in overdose, the delayed peak and longer duration of toxicity can have disastrous consequences. The mistakes made by the physician are in finding reassurance in the patient’s normal mental status despite hypotension and in not vigorously monitoring and treating the patient’s hemodynamic condition. If close attention to hypotension is not maintained, the cardiovascular status of the patient will continue to deteriorate until cardiopulmonary arrest becomes imminent. This occurrence has no precise explanation, but investigators have suggested that cerebrovascular vasodilation may be cerebroprotective, acting much like nimodipine does in subarachnoid hemorrhage.

Diagnostic testing is contingent on the necessity of treatment for hemodynamic instability. Once the patient’s airway, breathing, and cardiovascular status have been assessed and stabilized, testing should start with a 12-lead electrocardiogram (ECG) and chest radiography. Rapid determination of hyperglycemia and metabolic acidosis with capillary glucose and arterial blood gas analysis may demonstrate a severe calcium channel antagonist overdose. An elevated serum lactate concentration may be another marker of severe calcium channel antagonist overdose.4 Testing for serum concentrations of calcium channel antagonists is not clinically useful or available to guide treatment. Otherwise, standard laboratory testing for a general overdose is a good comprehensive approach.

**TREATMENT**

Because significant toxicity can occur after a small overdose of a cardiovascular drug, aggressive gastric decontamination is warranted, with activated charcoal as the primary agent. The general principle is that activated charcoal has the best efficacy if it is initiated within the first hour after ingestion. This is true but often not the circumstance, because most patients present beyond 1 hour from ingestion. If this is the case and the patient is still alert and hemodynamically stable, activated charcoal may prevent absorption, even if more than 1 hour because of sustained- or extended-release formulation.

Whole-bowel irrigation has been suggested for overdose of calcium channel antagonists because many of these drugs are sustained-release preparations. Whole-bowel irrigation is not indicated for a patient with hemodynamic instability because a significant amount of the drug has already been absorbed,5 and, therefore, the opportunity for prevention has passed. In addition, challenging a hypoperfused gastrointestinal system can have disastrous consequences, such as functional and physical obstruction by a calcium channel antagonist bezoar,6-9 as well as perforation. Generally speaking, no evidence indicates that any gastric decontamination procedure improves outcome in the patient with an overdose, and the risks must be assessed against the benefits.

Enhanced elimination is the removal of the toxin at a greater rate than inherently done by the body. The modalities are multiple-dose activated charcoal, urinary alkalization, and some form of hemodialysis. None of these techniques can adequately remove any of the calcium channel blockers or digoxin because of either too great a volume of distribution or protein binding or not enough enterohepatic circulation. Atenolol and sotalol are two β-receptor antagonists with a small volume of distribution and protein binding that could potentially be eliminated by hemodialysis.

The primary focus of treatment is the hypotension. The bradycardia and AV block usually improve as the hypotension improves. Atropine is frequently ineffective because the bradycardia and AV block are not related to increased vagal tone.

An antidotal treatment regimen is provided in Figure 148.2. This regimen emphasizes elemental calcium, either as calcium gluconate (30 mL of a 10% solution, or 3 g of calcium gluconate; 14 mEq elemental calcium) or calcium chloride (10 mL of a 10% solution, or 1 g; 13.5 mEq of elemental calcium). Calcium chloride should be administered through central venous access because it is an acidifying salt, which could cause necrosis of the peripheral vasculature. If the intravenous calcium boluses appear to have improved hemodynamic status, close monitoring for recrudescence of toxicity must be maintained, and further boluses must be given as necessary. An intravenous infusion of calcium is warranted only when it effectively treats the hypotension, and further boluses are required to support the blood pressure (Table 148.2). The serum calcium concentration should be monitored, but antidotal treatment rarely gives rise to clinically significant hypercalcemia.

Next, glucagon, in 5-mg intravenous boluses for two doses, may theoretically increase cardiac contractility by bypassing the antagonized calcium channels. When glucagon binds to its receptor, it activates cyclic adenosine monophosphate (cAMP). This may increase contractility by activating the phosphorylation cascade, which results in contraction of actin and myosin. Glucagon also stimulates release of endogenous insulin, a fortunate side effect explained later. Like a calcium infusion, a glucagon infusion is warranted only if a beneficial effect is seen after several boluses have been given. Glucagon can cause emesis because of relaxation of the lower esophageal sphincter.

Hyperinsulinemia euglycemia (HIE) therapy and catecholamines with inotropic and vasopressor activity are the next line of treatment for refractory hypotension in calcium channel antagonist overdose, but inotropics and vaspressors will be discussed first. A multicenter study compared dopamine and norepinephrine agents in all patients categorized as being in shock, regardless of cause. No difference was seen in the outcome (death at 28 days) for all patients in the study, but a predetermined subgroup analysis found greater mortality in patients with cardiogenic shock who were treated with dopamine.10 Because calcium channel antagonists can cause cardiogenic shock, norepinephrine is probably a good first choice. If clinically significant hypotension persists, adding more agents may be necessary. Cardiovascular data from diagnostic modalities such as transthoracic echocardiogram, pulmonary artery catheter, arterial catheter, and central venous catheter should dictate which cardiovascular agent is the most appropriate choice. Vasopressin has been used in human cases when peripheral vasoconstriction is indicated.11 Worsening of the cardiac index was demonstrated when vasopressin was used in an animal model to treat hypotension induced by calcium channel antagonist.12

Table 148.2 Antidotes, Treatments, Facts, and Formulas for Cardiovascular Drugs
In 1999, Yuan et al. described the first published use of high-dose insulin-euglycemia (HIE) therapy, in four patients with verapamil overdose and in one patient with amlodipine and atenolol overdose. HIE promotes inotropy by improving myocardial energy production. In addition, insulin has anti-inflammatory attributes that protect against apoptosis and ischemic reperfusion injury.

Subsequently, numerous case reports, reviews, and HIE regimens were published. HIE therapy has successfully reversed cardiogenic shock from a polydrug overdose, and historically it was used in multiple nontoxicologic conditions, such as acute myocardial infarction, post–cardiac surgery status, and septic shock. The superiority of HIE therapy for cardiogenic shock resulting from calcium channel antagonist...
toxicity was also demonstrated dramatically in animal models.22-28

Failure of HIE therapy often occurs when it is started as
rescue therapy and when the dose is inadequate.26 A small
prospective observational study of patients treated with HIE
therapy supports its safety.27 HIE therapy should be started
when boluses of calcium, glucagon, atropine, and intravenous
fluids have failed and the physician is considering a pressor
agent to improve refractory hypotension. The call to the phar-
macist to obtain the HIE infusion should be made when the
norepinephrine infusion is begun.

HIE therapy should start with a 1.0 unit/kg bolus of regular
insulin followed by an intravenous injection of 1 ampule of
50% dextrose in water (D50W). Immediately thereafter, an
infusion of 1.0 unit/kg/hour of regular insulin should begin,
along with an infusion of D50W at 100 mL/hour. Serum
glucose levels should be monitored every 15 minutes during
the first hour and then, if stable, every hour. A serum electro-
lyte analysis must be performed every hour to monitor serum
potassium, glucose, and other electrolyte values. Clinically
significant hypoglycemia has not been described with HIE
therapy. The amount of intravenous fluid administered must
be taken into consideration and the patient closely monitored
for signs and symptoms of pulmonary edema because the
calcium channel antagonist overdose can result in cardiogenic
or noncardiogenic pulmonary edema. The clinician must also
cogznizant of the limitations of HIE therapy in patients with
bradycardia, conduction abnormalities, and hypotension sec-
ondary to vasodilation.

When hemodynamic stability has been achieved, the vaso-
pressor therapy should be tapered and stopped because of the
potential detrimental effect on the myocardium from increased
oxygen demand and metabolic acidosis. Consequently, HIE
therapy can be gradually reduced when the patient becomes
hemodynamically stable. After the insulin has been discontin-
ued, the serum glucose concentration must be monitored con-
tinually for 4 to 6 hours after discontinuation of insulin.

A relatively new and novel antidote is increasingly being
used to treat highly lipophilic toxicants, such as verapamil.
Intralipid 20% was initially used for local anesthetic toxicity.
In patients and animal models, dysrhythmias, hypotension,
and even cardiac arrest from bupivacaine toxicity were
reversed rapidly with intralipid bolus. Three theories on how
this works have been proposed. One theory is the lipid forms
a “sink” in the vascular compartment that pulls the toxicant
from the tissues, where toxicity is occurring, and it becomes
trapped and eliminated. The second is that bupivacaine inhib-
its transport of fatty acids into mitochondria required for
energy production, and the exogenous lipids overcome this
inhibition. The third is that fatty acids increase calcium in
cardiac myocytes and therefore increase inotropy. Generally,
boluses are used, but an infusion is sometimes necessary.
Unfortunately, the safety of the boluses is unknown, but the
complications of intralipid use are generally from prolonged
total parenteral infusions.28

Young et al.29 reported a case of a 32-year-old man who
ingested 13.44 g of verapamil and bupropion, zolpidem, que-
tiapine, clonazepam, and benazepril. This patient had refrac-
tory hypotension after treatment with intravenous fluids,
glucagon, calcium, and norepinephrine. He was then admin-
istered 100 mL of 20% intralipid over 20 minutes and then
0.5 mL/kg/hour for almost 24 hours. His blood pressure
improved enough in 1 hour to begin weaning the norepineph-
rine, and the glucagon infusion was discontinued 2 hours after
intralipid administration.29 Consultation with a medical toxi-
cologist can be very helpful when considering HIE or intra-
lipid therapy.

Mechanical devices can also serve as adjunctive therapy in
calcium channel antagonist poisoning. Transcutaneous or
transvenous pacing is indicated when conduction is impaired
beyond pharmacologic reversal. More invasive mechanical
measures to support the cardiovascular system are an intraaor-
tic balloon pump, extracorporeal membrane oxygenation, and
cardiopulmonary bypass.

Often, the lack of mental status impairment coinciding with
hypotension can beguile the physician into believing that the
patient is not suffering severe clinical effects of a calcium
channel antagonist overdose. At this point, elective intubation
should be considered, before emergency intubation has to be
performed during cardiopulmonary arrest.

DISPOSITION

Asymptomatic patients who have ingested an immediate-
release calcium channel antagonist can be monitored for 6
hours in the emergency department. After ingestion of a
sustained-release calcium channel antagonist, the asymptomatic
patient should undergo cardiovascular monitoring for
18 to 24 hours.1 All symptomatic patients with cardiovascular
instability after cardiovascular drug overdose should be admit-
ted to the intensive care unit for cardiovascular monitoring,
diagnostic studies, and treatment until the effects have resolved.

SPECIAL CONSIDERATIONS: PEDIATRIC
OVERDOSE

The 2009 National Poison Center Database System data noted
one pediatric fatality of a suicidal 16-year-old girl, who
ingested verapamil and an unknown drug.1 The clinical con-
sequences of accidental pediatric calcium channel antagonist
 ingestions depend on the dose.

One must consider that the major flaw of studies attempting
to demonstrate a dose response of accidental pediatric drug
ingsestions is that many of the reports are nonexposures. The
caretaker of the child may report the exposure to a poison
center if a pill is missing and the child is implicated by his or
her presence in the vicinity. If the child did not take the drug,
the case may be referred to as having a good outcome, and
the “dose” considered safe.30

A guideline for pediatric ingestions of calcium channel
antagonists states that immediate referral to a health care
center is necessary if the dose exceeded the usual therapeutic
dose or was considered equal to or greater than the lowest
toxic dose (whichever is lower).3 At these doses, significant
bradycardia or hypotension may occur. Accidental single
 ingestions of calcium channel antagonists in children are con-
sidered lethal enough to be fatal.31

Realistically, administration of activated charcoal is prudent
if the patient has presented within 1 hour of the ingestion.
Whole-bowel irrigation may be considered for ingestion of a
modified-release product but is technically difficult. If the
patient is near adult size, has ingested a potentially
life-threatening amount of a calcium channel antagonist, and presents within 1 hour of the ingestion, gastric lavage may be helpful for gastrointestinal decontamination. However, many kits are not available, and the “act” of gastric lavage is labor intensive and does not change clinical outcome.

Cardiovascular monitoring for 6 to 8 hours for immediate-release medications and for at least 24 hours for sustained-release medications should reveal delayed toxicity. All symptomatic children should be admitted for cardiovascular monitoring and treated with standard therapy.

**β-RECEPTOR ANTAGONISTS**

**PATHOPHYSIOLOGY**

As their name suggests, β-receptor antagonists antagonize the effects of beta agonists by competing for β-adrenergic receptors. The result within the cell is a decrease in cAMP, which leads to decreased intracellular flow of calcium and actin-myosin contraction. The effects are bradycardia in the nodal cells and decreased contractility in the cardiac myocytes. Consequently, the attenuated stroke volume combined with a decreased heart rate elicits a decline in cardiac output and the promotion of cardiogenic shock.

β-Receptor antagonism is not the only pharmacologic mechanism of toxicity seen after β-receptor antagonist overdose. α-Receptor antagonism, sodium or potassium channel antagonism, central nervous system penetration leading to seizures with altered mental status, and sympathomimetic stimulation may also occur (Table 148.3).

Most of the actively prescribed β-receptor antagonists are first metabolized by hepatic enzymes and then processed by the kidney. One exception is atenolol, which is exclusively excreted in the urine. Atenolol also has a volume of distribution and protein-binding properties that permit hemodialysis as a method of enhancing elimination. Esmolol has the unique metabolic characteristic of rapid metabolism in the serum by red blood cell esterases.

**PRESENTING SIGNS AND SYMPTOMS**

Immediate-release products should cause signs and symptoms within 6 hours. Unfortunately, most β-receptor antagonists are of modified-release formulation. They have some pharmacologic effect during the first 6 hours after ingestion, but the peak serum concentration is delayed, and the pharmacologic effect may last longer than with immediate-release formulations.

Cardiovascular signs and symptoms are the predominant clinical manifestations of β-receptor antagonist toxicity. As with the calcium channel antagonists, cardiogenic shock results primarily from a decrease in cardiac output secondary to diminished stroke volume and heart rate. Patients may complain of chest pain, shortness of breath, palpitations, and dizziness in relation to their bradycardia and hypotension. The ECG may demonstrate sinus arrest, sinus bradycardia, junctional bradycardia, and all degrees of AV block.

If the β-receptor antagonist also possesses pharmacologic activity at other receptors, the clinical picture will be complicated. α-Receptor antagonism after ingestion of carvedilol or labetalol may contribute to hypotension by causing peripheral vasodilation. Propranolol can cause sodium channel antagonism (membrane-stabilizing effect). This pharmacologic activity is exhibited clinically as a prolonged QRS complex on the cardiac monitor and hypotension, much as in a tricyclic

antidepressant overdose. The cardiac rhythm can potentially degenerate into ventricular tachycardia.

Sotalol is infamous for antagonizing the delayed rectifier potassium channels in the myocardium. The results are a prolonged QT interval and a higher risk of torsades de pointes (polymorphic tachycardia), monomorphic ventricular tachycardia, ventricular fibrillation, and asystole. These clinical effects can also be delayed and prolonged. In one case report, the onset of ventricular dysrhythmias occurred 4 to 9 hours after ingestion and did not normalize until 100 hours from the time of ingestion.33

Observation of sympathomimetic effects after β-receptor antagonist ingestion is rare because of the uncommon clinical use of β-receptor antagonists with intrinsic sympathomimetic activity, such as acebutolol, oxprenolol, penbutolol, and pindolol. Patients who have ingested these agents may have tachycardia, hypertension, tremor, and, possibly, some antidotal efficacy because some beta-antagonists can antagonize their own toxic effects.

Some of the β-receptor antagonists, such as propranolol, are more lipophilic and can cross the blood-brain barrier. Symptoms of delirium, coma, and seizures have been reported in patients with overdose of highly lipophilic β-receptor antagonists. Other less common clinical effects reported are respiratory depression, bronchospasm, hypoglycemia in children, and hyperkalemia.

TIPS AND TRICKS

β-Receptor Antagonist Toxicity

• Obtain a capillary blood glucose measurement to detect euglycemia or hypoglycemia.
• Identify the unique toxicity of each β-receptor antagonist.
• Do not start infusions of glucagon or calcium until multiple boluses have successfully reversed the toxicity.
• Avoid isoproterenol as an antidotal agent.
• Hyperinsulinemia/euglycemia therapy works to treat hypotension from β-receptor antagonist toxicity.
• Atenolol and sotalol have characteristics that allow the use of hemodialysis to enhance elimination.
• Monitor electrolyte concentrations and excess intravenous fluid closely.
• An echocardiogram, central venous pressure monitor, and pulmonary artery catheter can be helpful for diagnosing and treating the multiple components of the shock that occurs during β-receptor antagonist toxicity.
• If the β-receptor is lipophilic (e.g., propranolol), intralipid therapy may be effective at reversing toxicity.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The differential diagnosis (see also Fig. 148.1) of β-blocker toxicity includes the following: congestive heart failure and pulmonary edema, cardiogenic or hemorrhagic shock, epidural hematoma, epidural and subdural infections, meningitis, other causes of electrolyte abnormalities, and overdoses of cardiac glycosides, calcium channel blockers, carbamazepine, carbon monoxide, cocaine, and antidepressants.

Measurements of serum concentrations of β-receptor antagonists are generally unavailable and unhelpful in the emergency department. No laboratory studies correlate beta-blocker concentrations with outcomes. Additional standard laboratory testing as for a general overdose is advisable, with particular focus on hypokalemia and hypoglycemia, along with other electrolytes. Cardiac enzymes should be obtained to evaluate for myocardial infarction. Therapeutic interventions and patient stabilization are the priorities. As resuscitation continues, a 12-lead ECG and cardiac monitoring may demonstrate bradycardia, AV conduction abnormalities, and prolonged QRS and QTc intervals. Monitoring for hypocalcemia, hypokalemia, and hypomagnesemia assists in treatment of coexisting causes of prolonged QTc intervals.

TREATMENT

In a hemodynamically stable patient who has overdosed on a β-receptor antagonist, aggressive gastric decontamination is warranted. The limits of gastric decontamination use in calcium channel antagonist overdose apply to that in β-receptor antagonist overdose.

The end result of overdose of either β-receptor or calcium channel antagonists is shock, despite their different mechanisms of action. Because these agents have a final common pathway, antidotal therapy is analogous. Treatment follows the same algorithm as shown in Figure 148.2. Atropine can be used initially, followed by intravenous calcium, glucagon, HIE, and catecholamines with chronotropic and inotropic effects for refractory bradycardia and AV block. Unfortunately, severe bradycardia and AV block are often refractory to pharmacological efforts, and transcutaneous or transvenous pacing may be required.

Calcium reverses toxicity through circumvention of the β-receptor antagonist by entering open L-type calcium channels and increasing the cytoplasmic concentration of calcium, thus leading to contraction of the myosin-actin apparatus. Fear of hypercalcemia should not prohibit the use of elemental calcium as antidotal treatment of β-receptor antagonist toxicity.

Glucagon increases cardiac contractility by bypassing the antagonized β-receptors through activation of cAMP by agonism at the glucagon receptors. This activation increases contractility by activating the phosphorylation cascade, which leads to contraction of actin and myosin. Glucagon also stimulates release of endogenous insulin, a beneficial side effect. Unfortunately, glucagon is often ineffective at reversing β-receptor antagonist toxicity.34

Vasopressin was used in an experimental animal model poisoned by propranolol.35 The investigators discovered equally dismal survival rates for treatment with glucagon and vasopressin.

HIE therapy is a therapeutic approach for β-receptor antagonist toxicity. Animal models demonstrated the superiority of HIE therapy over glucagon, epinephrine, and saline solution for the reversal of the toxic effects of propranolol.36 Yuan et al.13 reported effective reversal of the toxic effects of a β-receptor and calcium channel antagonist coingestion with this treatment. Despite the absence of the diabetic
ketoacidosis metabolic state produced by calcium channel antagonist, HIE therapy is believed to be just as effective in β-receptor antagonist intoxication. Mechanistically, this antihypertensive therapy improves inotropy by promoting aerobic utilization of glucose by the myocardial myocytes, inhibition of fatty acid metabolism, decreased lactate production, and improvement of myocardial oxygen utilization without increasing oxygen demand. The mild hypokalemia that occurs also may offer a trophic effect favoring myocardial cell function.

The evidence is convincing that HIE therapy is a remedy for a depressed inotropic state, but its reversal of the myriad other toxicologic effects mediated by β-receptor antagonists, such as bradycardia and conduction abnormalities, is unsubstantiated. The clinician must be aware of the limitations of HIE treatment and must treat other toxic effects appropriately. Vigilance in monitoring for the potential adverse effects of HIE therapy in this setting must be greater than for other uses of HIE because of the lack of insulin resistance seen in most β-receptor antagonist intoxications.

A case of cardiac arrest induced by nebivolol, diazepam, and baclofen was reversed with a bolus of intralipid 20% and HIE therapy. Intralipid therapy should be considered in lipophilic β-receptor antagonist overdose.

### DISPOSITION

The asymptomatic patient who has no cardiovascular effects of overdose with an immediate-release or sustained-release β-receptor antagonist or sotalol can be discharged after 6, 8, or 12 hours of observation, respectively. All symptomatic patients should be admitted for intensive care monitoring of the hemodynamic effects.

### PRIORITY ACTIONS

**Treatment of β-Receptor Antagonist Toxicity**
- Supportive care of airway, breathing, and circulation is the first critical step.
- Gastric decontamination is critical in the patient presenting with hemodynamic instability.
- Administer doses of calcium and glucagon adequate to elicit a clinical response.
- Consider HIE therapy for cardiogenic shock.
- Consider norepinephrine as the first choice for vasopressor therapy.
- Electrical pacing is an option for symptomatic β-receptor antagonist bradycardia.

### DIGOXIN

#### PATHOPHYSIOLOGY

Digoxin is a cardiac glycoside that was historically used for the treatment of congestive heart failure and for rate control in atrial fibrillation. Despite a reduction in popularity, digoxin is still clinically effective for many patients. Natural cardiac glycosides provide another possible exposure source (Box 148.1).

#### PRESENTING SIGNS AND SYMPTOMS

Patients may be asymptomatic from minutes to hours after ingestion of digoxin. Gastrointestinal symptoms are common, and patients have nausea and vomiting. Patients may complain of changes in vision, especially chromatopsia and xanthopsia.
C EME
digoxin concentration can slightly almost the manifest toxicity to toxicities has any digoxin have Neonates:
only digoxin serum toxicity acute challenge. Manifestations can be similar to those of patients and presents with nonspecific complaints that make diagnosis for digoxin toxicity.

tional ventricular tachycardia is considered pathognomonic monly reported dysrhythmias are listed in sinus node to the A V node and the His-Purkinje fibers. Com-
tion can be impaired anywhere along the pathway from the conductivity are a mixture of bradydysrhythmias, tachydysrhythmias with conductive blockade, and hypotension. Cardiac conduc-
tivity are a mixture of bradydysrhythmias, tachydysrhythmias from the direct effect of the digoxin. The cardiac effects are usually represented by symptoms such as palpitations, chest
pain, dizziness, and dyspnea. The cardiac signs in acute toxicity are a mixture of bradydysrhythmias, tachydysrhythmias with conductive blockade, and hypotension. Cardiac conduc-
tion can be impaired anywhere along the pathway from the sinus node to the AV node and the His-Purkinje fibers. Commonly reported dysrhythmias are listed in Box 148.2. Bidirec-
tional ventricular tachycardia is considered pathognomonic for digoxin toxicity.

The patient with chronic digoxin toxicity is generally older and presents with nonspecific complaints that make diagnosis a challenge. Manifestations can be similar to those of patients with acute digoxin toxicity, but they differ in patients with more neuropsychiatric complaints, such as delirium, confusion, drowsiness, and hallucinations, and visual complaints. Ventricular tachydysrhythmias are more common in patients with chronic toxicity.

The patient with acute-on-chronic toxicity may have clinical manifestations of both the other types of toxicity. In general, acute-on-chronic toxicity is clinically more like acute digoxin toxicity.

### TIPS AND TRICKS

**Digoxin Toxicity**

- If the patient has life-threatening digoxin toxicity, treatment with the digoxin-specific Fab fragments is the first priority.
- Acute-on-chronic and acute digoxin toxicities have the same manifestations, but acute and chronic digoxin toxicities have distinct symptoms, dysrhythmias, and laboratory findings.
- The digoxin serum concentration may be only slightly elevated or normal in chronic digoxin toxicity.
- Digoxin toxicity can manifest as almost any dysrhythmia.
- The equilibrium concentration of serum digoxin occurs 6 hours after ingestion, and is inaccurate after administration of digoxin-specific Fab fragments.
- Recurrence of toxicity is typically related to underdosing of digoxin-specific Fab fragments.
- The indications and treatment of digoxin toxicity and con-
comitant renal impairment are the same.
- No method of enhancing elimination, including hemodial-

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Before considering digoxin toxicity, one must first define the different types of digoxin toxicity. They are as follows:

**Acute digoxin toxicity:** A patient who is naive to the medica-
tion is exposed to a single acute ingestion.

**Acute-on-chronic digoxin toxicity:** The serum digoxin concen-
tration increases because of renal failure or an inadvertent or intentional increase in dose. The clinical presentations for this and acute toxicity are similar, so management is similar.

**Chronic digoxin toxicity:** A patient has clinical signs of digoxin toxicity with a mildly elevated or therapeutic serum digoxin concentration.

The differential diagnosis includes other cardiovascular drugs (see Fig. 148.1), acute renal failure, hypercalcemia, hyperkalemia and hypokalemia, hypernatremia and hypona-
tremia, and hypomagnesemia.

An ECG and continuous cardiac monitoring are crucial initial steps in determining cardiovascular instability in a patient with digoxin toxicity. These tests alert the clinician to

### BOX 148.2 Dysrhythmias Associated with Digoxin Toxicity

| Atrial fibrillation | Delayed afterdepolarizations |
| Atrial flutter      | Bidirectional ventricular    |
| Atrial tachycardia with atrioventricular block | tachycardia (pathognomonic) |
| Premature ventricular tachycardia | Bigeminy |
| Ventricular tachycardia | Sinus arrest |
| Ventricular fibrillation | Sinus bradycardia |

Some mild confusion, weakness, and dizziness also can occur from the direct effect of the digoxin. The cardiac effects are usually represented by symptoms such as palpitations, chest pain, dizziness, and dyspnea. The cardiac signs in acute toxicity are a mixture of bradydysrhythmias, tachydysrhythmias with conductive blockade, and hypotension. Cardiac conduction can be impaired anywhere along the pathway from the sinus node to the AV node and the His-Purkinje fibers. Commonly reported dysrhythmias are listed in Box 148.2. Bidirectional ventricular tachycardia is considered pathognomonic for digoxin toxicity.

The patient with chronic digoxin toxicity is generally older and presents with nonspecific complaints that make diagnosis a challenge. Manifestations can be similar to those of patients...
dysrythmias that require treatment with digoxin-specific Fab fragments and supportive care. A chest radiograph demonstrates any evidence of cardiac failure related to the digoxin overdose.

Laboratory testing should be performed expeditiously in any digoxin overdose, with the focus on serum potassium, magnesium, and digoxin concentrations. Rapid assessment of serum potassium concentration helps determine the severity of the toxicity. In acute digoxin poisoning, the serum potassium value is elevated. If this value is 5 mEq/L or greater, digoxin-specific Fab fragment therapy should be considered. In chronic digoxin toxicity, the serum potassium concentration is often low, usually because of concomitant ingestion of a diuretic. The hypokalemia, in effect, worsens the inhibition of the Na⁺,K⁺-ATPase pump.

Obviously, assessment of the serum digoxin concentration is essential. The therapeutic range is 0.5 to 2.0 ng/mL. The steady-state serum concentration is most accurate 6 hours after ingestion. A serum digoxin concentration of 10 ng/mL at steady state or 15 ng/mL at any time is generally accepted as an indication for digoxin-specific Fab fragment therapy.

A serum digoxin concentration measured in blood collected after administration of digoxin-specific Fab fragments is clinically not useful and is uninterpretable. The assay often measures the antidote, the drug, and the combination of the two, and it interprets one or all of them as the serum digoxin concentration; the result may be higher than, lower than, or within the therapeutic range for serum digoxin.

Screening for accompanying hypomagnesemia is important because this condition may lead to refractory hypokalemia, blockade of inward calcium channels and intracellular binding sites, blockade of extracellular movement of potassium, decrease in myocardial irritability, and a prolonged QT interval. Hypomagnesemia increases myocardial uptake of digoxin and worsens dysfunction of the Na⁺,K⁺-ATPase pump.

**TREATMENT**

A reasonable approach is to consider activated charcoal to minimize intestinal absorption in a person presenting within 1 hour of digoxin overdose. Gastrointestinal decontamination may be limited by emesis induced by the digoxin. Whole-bowel irrigation is also not indicated because of rapid absorption of digoxin and the availability of other, more practical options.

The successful use of digoxin-specific Fab fragments to treat digoxin intoxication was first described in 1976. Since that time, multiple studies have demonstrated its safety and efficacy. The best antidote to administer for digoxin toxicity is digoxin-specific Fab fragments, whether for hypotension, dysrhythmias, serum digoxin concentration, or hyperkalemia.

Two commercial formulations of digoxin-specific Fab fragments are available, Digibind and DigiFab. Literature for both products warns against anaphylaxis and administration of the agents to people with papain, chymopapain, or papaya allergies. Other adverse events associated with administration of digoxin-specific Fab fragments occur from removal of the therapeutic benefit of the digoxin—for example, recurrence of congestive heart failure or atrial fibrillation with a rapid ventricular response.

</table>

After an acute ingestion of digoxin, an empirical bolus of 5 to 10 vials (up to 10 to 20 vials) of digoxin-specific Fab fragments is indicated in the patient with life-threatening toxicity. When the clinical situation allows determination of a serum digoxin concentration, the simple dosing calculation is as follows:

\[
\text{Dosage} = \frac{\text{Patient weight (kg)}}{100} \times \text{Serum concentration (ng/mL)}
\]

The number obtained is the number of vials needed to treat the patient.

When the amount ingested is known, the digoxin-specific Fab fragment dose can be calculated by knowing that 1 vial will bind 0.5 mg, or multiply the amount ingested by 2 (see Table 148.4 for determining dose). In the noncritical patient, digoxin-specific Fab fragments should be reconstituted with 4 mL of saline, used immediately or within 4 hours if refrigerated, and infused over 30 minutes. Indications for digoxin-specific Fab fragments are listed in Box 148.3. A clinical response should be seen within 60 minutes.

In patients with chronic digoxin toxicity, calculating the dosage of digoxin-specific Fab fragments with the serum digoxin concentration often overshoots the amount needed to reverse toxicity. The concern is precipitating an exacerbation of hypokalemia, congestive heart failure, or rapid atrial fibrillation. A prudent approach is to administer 1 or 2 vials initially. If toxicity has resolved or an adverse effect has occurred, no further vials should be given. If no adverse effect has arisen and toxicity has not resolved, 1 or 2 vials more are indicated.

Many patients presenting with acute-on-chronic digoxin toxicity have renal failure. Digoxin-specific Fab fragments should not be withheld in these patients because of concern about the inability of the kidney to remove the digoxin-Fab complex. This complex cannot be removed by dialysis either. Mild recrudescence of toxicity has been reported when the Fab fragments become unbound and are eliminated faster than digoxin. However, multiple publications cite inadequate
dosing as a much greater risk factor for recrudescence, and the transient rise in serum digoxin concentration has been within the therapeutic range and not clinically significant.47,48 Simply administering another dose of digoxin-specific Fab fragments or giving conscientious supportive care may be the only additional therapy required. These patients typically have transient renal impairment, and once it has resolved, the digoxin, Fab fragments, and Fab-digoxin complex are removed. Finally, the use of digoxin-specific Fab fragments can be cost effective.49

Atropine may be effective in treating symptomatic bradycardia early in acute digoxin toxicity because it increases vagal tone. Treatment of bradycardia with atropine later in an acute presentation or in chronic digoxin toxicity is often unsuccessful because the bradycardia is not related to vagal tone but to other toxic effects of the digoxin. The ultimate treatment of symptomatic bradycardia is administration of digoxin-specific Fab fragments.

Transcutaneous pacing and transvenous pacing have been used to treat symptomatic bradycardia, but transvenous pacing must be used with caution. One study reported a higher mortality rate in patients receiving transvenous pacing because of dysrhythmias.50 In addition, iatrogenic complications (36%) were seen in patients receiving transvenous pacing. This danger of transvenous pacing in the setting of digoxin toxicity has come into question, however. A retrospective review of 70 patients was divided into two groups. One group received transvenous pacing, and the other did not. No deaths occurred in the paced group, and 2 patients in the nonpaced group died of ventricular dysrhythmias, but no statistically significant difference was seen. Transvenous pacing was not an independent predictor of prognosis. The investigators reported no complications of venous thromboembolism, cardiac rupture, or infection. The investigators speculated that the previous study had poor outcomes from overdrive transvenous pacing, which can stimulate ventricular dysrhythmias. In their study, the heart rate was limited to 60 beats/minute.51

Unstable supraventricular or ventricular dysrhythmias can be treated by electrical cardioversion. Because of the hyperexcitability of the digoxin-poisoned myocyte and nodal tissue, however, low current is recommended. The concern is that high voltages may induce refractive lethal ventricular tachycardia.

The use of intravenous calcium in the treatment of hyperkalemia in the digoxin-poisoned patient was considered a contraindication during much of the twentieth century. The concern about calcium administration in digoxin toxicity is an additive toxic effect. During digoxin toxicity, patients already have a dysfunction in intracellular calcium regulation along with an elevated calcium concentration. If more calcium is added to this hypercontractile state, a condition referred to as “stone heart” could be produced. This concern was supported by an early human case series and two animal studies, all published before 1940.52-54

More recently, a case report and animal study found no synergistic effect of calcium and digoxin toxicity resulting dysrhythmia or death during treatment of hyperkalemia.55,56 A retrospective review of 159 patients with digoxin toxicity over 17.5 years compared dysrhythmia in 1 hour from calcium or mortality in the patients treated with calcium versus no calcium. The investigators discovered no dysrhythmias and similar mortality in both groups and increased mortality in patients with higher serum potassium.57

An excellent review of the literature on this topic specified that the rate and amount of calcium administered is probably more contributory to dysrhythmias or the stone heart. The reviewers reasonably concluded that if the patient has signs of hyperkalemia toxicity, such as loss of P waves, peaked T waves, or a widened QRS complex, treatment with calcium should be undertaken. If the patient has manifestations of digoxin toxicity such as ectopic beats or ventricular tachycardia, then digoxin-specific Fab fragments should be the first-line treatment.58 Ultimately, the anxiety created by calcium combined with digoxin toxicity is probably much greater than the true risk. This risk can be minimized even more by using other methods to decrease the serum potassium. If the patient is hemodynamically stable, administration of digoxin-specific Fab fragments should be the first choice to treat the hyperkalemia and all the other components of digoxin toxicity.

Treatment of hypotension should also include increasing the preload with intravenous fluids and pharmaceutical agents that have inotropic and vasopressor properties, such as norepinephrine. Little is known about the effectiveness of other antidotes, such as glucagon, to treat hypotension or bradycardia. Hypomagnesemia should be treated in standard fashion, with 2 g of intravenous magnesium given over 20 minutes.

**SECTION XV ■ TOXICOLOGIC EMERGENCIES**

**PRIORITY ACTIONS**

**Treatment of Digoxin Toxicity**

- Supportive care of airway, breathing, and circulation is the first critical step.
- Gastric decontamination is critical in the patient presenting with hemodynamic instability, but refrain from challenging the gastrointestinal system of a patient with hemodynamic instability.
- Assess serum potassium and magnesium levels immediately.
- Digoxin-specific Fab fragments are the definitive treatment for all clinical manifestations of digoxin toxicity.
- Dosage of digoxin-specific Fab fragments can be (1) empirical (5-10 vials) in the hemodynamically unstable patient, (2) calculated according to the amount of digoxin bound by 1 vial, or (3) calculated from the serum digoxin concentration.
- Decrease the current for cardioversion in patients with digoxin toxicity.
- Use a small number of vials (1-2) to treat patients with chronic digoxin toxicity.

**DISPOSITION**

If the patient is asymptomatic and has no clinical findings of acute digoxin toxicity, with a serum digoxin concentration at 6 hours in the therapeutic range, the physician is probably safe to reclassify this patient medically as no longer having digoxin...
toxicity. Of course, this decision depends on a reliable history. A 6-hour period of monitoring is adequate because the latest peak effect from oral digoxin is 6 hours, and that from intravenous digoxin is 3 hours. Clinical effects should appear before this time.

All symptomatic patients with clinical evidence of acute or chronic digoxin toxicity should be admitted to a monitored setting. The symptomatic patient who has life-threatening signs of toxicity and has been treated with digoxin-specific Fab fragments should be admitted to the intensive care unit.

The symptomatic patient with relatively stable vital signs and cardiac rhythm should be admitted to a unit with cardiac monitoring capabilities with an adequate dose of digoxin-specific Fab fragments available at the bedside.

difference in prevalence, which had decelerated, was noted. However, the year 2010 also saw a dramatic increase in the use of ecstasy, or 3,4-methylenedioxymethamphetamine (MDMA). Researchers believe that this shift may be the result of the adolescent population’s perception of a lower risk associated with MDMA.

Prescription agents continue to be a source of misuse. The rate of misuse of combination sympathomimetic products rose from 2009 to 2010. Overall, sympathomimetics remain a public health concern. According to the Drug Abuse Warning Network, these drugs accounted for almost 30% of all emergency department (ED) substance-related visits in 2009.

**PATHOPHYSIOLOGY**

The biogenic amines (histamine, tyrosine, and serotonin) and the catecholamines (epinephrine, norepinephrine, and dopamine) are found within the central nervous system (CNS) and their synthesis, release, and metabolism are very similar. Tyrosine is converted into dopamine, and subsequently norepinephrine, whereas serotonin is derived from tryptophan and resides in separate vesicles. Despite differences in synthesis and packaging, calcium is the common stimulus for exocytosis. Once an amine is released into the synapse, reuptake can occur through transport proteins. Intracellularly, these products are either metabolized by the enzyme monoamine oxidase or repackaged and recycled. In the periphery, these amines may undergo extracellular metabolism by catechol-O-methyltransferase.

Sympathetic stimulation triggers the release of epinephrine and norepinephrine from the adrenal medulla. However, norepinephrine can also be released into the circulation, with effects consistent with α-adrenergic stimulation (i.e., vasoconstriction). Dopamine, found within nerve terminals in the CNS, is also present in the periphery. Excessive dopamine concentrations in the CNS can manifest as psychosis, which is clinically indistinguishable from primary psychosis. Similarly, serotonin found both centrally and peripherally can have a broad spectrum of effects modulating mood, appetite, sleep, and thermoregulation. In the CNS, an abundance of serotonin can induce euphoria, or an elevated mood.

Pharmacotherapeutics can mimic catecholamine release by stimulating release, inhibiting metabolism, and impairing reuptake. The specific clinical effects produced by a sympathomimetic agent are related to its pharmacology, whereas the...
relative effect on the two distinct adrenergic receptors, \( \alpha \) and \( \beta \), can be used to predict the clinical response. Generally, \( \alpha \)-adrenergic receptor agonism results in vasoconstriction, whereas the inverse effect is appreciated with \( \beta \)-adrenergic receptor stimulation. The resultant vasodilatation produces hypotension and tachycardia. \( \beta \)-Adrenergic agonism can also lead to hypokalemia, hyperglycemia, tremor, and acidemia.

Sympathomimetics may act directly, indirectly, or in combination to produce sympathomimesis. Direct-acting sympathomimetics are the catecholamines epinephrine and norepinephrine, directly administered to the patient. Indirect-acting sympathomimetics are agents that either increase the release of endogenous catecholamines or impair their reuptake. In addition, indirect-acting sympathomimetics can trigger the release of other biogenic amines such as serotonin and dopamine. Finally, mixed-acting sympathomimetics exert their effect through direct and indirect-acting properties. Despite these underlying differences, the clinical presentation can be virtually indistinguishable. Clinical manifestations may also vary according to the location where the neurotransmitter predominance occurs.

### PRESENTING SIGNS AND SYMPTOMS

Tachycardia, hypertension, diaphoresis, mydriasis, hyperthermia, and psychomotor agitation characterize the sympathetic toxidrome, which can be further divided according to \( \alpha \) and \( \beta \)-adrenergic receptor effects. \( \alpha \)-Adrenergic subtype 1, or \( \alpha_1 \), receptor agonism results in vasoconstriction, whereas postsynaptic \( \alpha_2 \) agonism results in hypotension and sedation. These effects are classically observed in the therapeutic use of clonidine. Like \( \alpha \) receptors, \( \beta \)-adrenergic receptors have clinically distinct subtypes, 1 and 2. \( \beta_1 \) agonism increases cardiac output by improving chronotropy. \( \beta_2 \) agonism is specifically responsible for vasodilation, as well as secondary effects such as hypokalemia, hyperglycemia, acidemia, and tremor.

Methylxanthine exposure is virtually indistinguishable from \( \beta \) stimulation because of a shared final pathway, which increases intracellular cyclic adenosine monophosphate. Methylxanthines also result in increased circulating catecholamines and inhibit adenosine receptors. Potential clinical effects associated with sympathomimetics are listed in Box 149.2.

As a result of hypertension and tachycardia, vascular events can occur during exposure to a sympathomimetic. Cocaine use is associated with myocardial infarction, coronary artery dissection, aortic dissection, cardiomyopathy, splanchnic infarction, cerebrovascular accidents, and cerebrovascular hemorrhage. The vasoconstriction and resultant hypertension make \( \beta \)-adrenergic blockade a precarious pharmacologic intervention.

Similar to the cardiovascular effects, some of the CNS effects are secondary to hypertension and vasoconstriction, leading to CNS ischemia and hemorrhage. Animal studies suggested an association between extreme CNS stimulation and the development of seizures, hyperthermia, and increased mortality. Aggressive therapy should focus on inhibiting CNS hyperactivity, thus reducing morbidity and mortality. Other CNS effects associated with the cessation of amphetamines and cocaine use are termed withdrawal or “washout.”

*No longer available.*
resultant lethargy and depressed mood are secondary to catecholamine depletion.

Metabolic derangements during sympathomimetic exposure resemble the fight-or-flight response. The most common metabolic changes, hyperglycemia and hypokalemia, result from a surge in epinephrine. When the metabolic demands outstrip the supply of energy substrates, metabolic acidosis can develop. Because of the body’s ability to achieve homeostasis, however, these metabolic effects usually do not require intervention.

Similarly, in combination with psychomotor agitation, this increased demand and activity can result in tremor, muscle rigidity, and rhabdomyolysis. Additionally, the syndrome of inappropriate antidiuretic hormone (SIADH) has been observed in association with MDMA use, as reflected by hyponatremia and inappropriately concentrated urine in the setting of euvolemia. Patients stereotypically develop symptoms the day after exposure, and they present with either altered mental status or seizures.

Differential Diagnosis and Medical Decision Making

The differential diagnosis of the patient with a sympathomimetic toxidrome is extensive (Box 149.3). It includes a spectrum of disease ranging from febrile illness to delirium.

Most individuals who misuse or abuse sympathomimetics do not present to the ED; those who do are usually symptomatic. While the physician is considering the extensive differential diagnosis and clinical effects, aggressive measures should be taken to evaluate and stabilize these individuals (Fig. 149.1). Urine screening for sympathomimetics, with the exception of cocaine, is fraught with error and misinterpretation. A negative result does not exclude an exposure, whereas a positive result does not confirm causation of the patient’s clinical presentation. Therefore, this test is not recommended in the evaluation of a potentially poisoned adult patient.

If the patient is too agitated to allow a thorough evaluation, a bedside glucose measurement should be performed to exclude hypoglycemia. An intravenous line should be placed and secured, to allow parenteral administration of benzodiazepines to control the patient’s behavior and thereby prevent further morbidity to the patient and hospital staff.

If the patient is well controlled or does not require sedation, a complete history and physical examination should be obtained while the physician pays close attention to the presence of a sympathomimetic toxidrome. The presence of this toxidrome supports the diagnosis of exposure but does not exclude other possibilities.

All patients with a potential exposure should have a 12-lead electrocardiogram (ECG) performed. Signs of ischemia, infarction, or electrolyte disturbance may be present despite the lack of patient endorsement. In the case of a suspected sympathomimetic toxidrome, patients should be resuscitated with isotonic fluid. Most of these individuals are volume depleted from agitation, diaphoresis, and increased metabolic demand. The only situation in which fluid resuscitation should not be initiated before laboratory evaluation is in the individual suspected of having SIADH from MDMA use.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The differential diagnosis of the patient with a sympathomimetic toxidrome is extensive (Box 149.3). It includes a spectrum of disease ranging from febrile illness to delirium.

Most individuals who misuse or abuse sympathomimetics do not present to the ED; those who do are usually symptomatic. While the physician is considering the extensive differential diagnosis and clinical effects, aggressive measures should be taken to evaluate and stabilize these individuals (Fig. 149.1). Urine screening for sympathomimetics, with the exception of cocaine, is fraught with error and misinterpretation. A negative result does not exclude an exposure, whereas a positive result does not confirm causation of the patient’s clinical presentation. Therefore, this test is not recommended in the evaluation of a potentially poisoned adult patient.

If the patient is too agitated to allow a thorough evaluation, a bedside glucose measurement should be performed to exclude hypoglycemia. An intravenous line should be placed and secured, to allow parenteral administration of benzodiazepines to control the patient’s behavior and thereby prevent further morbidity to the patient and hospital staff.

If the patient is well controlled or does not require sedation, a complete history and physical examination should be obtained while the physician pays close attention to the presence of a sympathomimetic toxidrome. The presence of this toxidrome supports the diagnosis of exposure but does not exclude other possibilities.

All patients with a potential exposure should have a 12-lead electrocardiogram (ECG) performed. Signs of ischemia, infarction, or electrolyte disturbance may be present despite the lack of patient endorsement. In the case of a suspected sympathomimetic toxidrome, patients should be resuscitated with isotonic fluid. Most of these individuals are volume depleted from agitation, diaphoresis, and increased metabolic demand. The only situation in which fluid resuscitation should not be initiated before laboratory evaluation is in the individual suspected of having SIADH from MDMA use.

BOX 149.2 Clinical Manifestations of Sympathomimetics

Cardiovascular
  - Hypertensive emergencies
  - Acute coronary syndrome
  - Cerebrovascular accident
  - Tachycardias, dysrhythmias
  - Vasospasm and ischemia to end-organs

Central Nervous System
  - Altered mentation
  - Anxiety
  - Mania
  - Psychosis
  - Agitated delirium
  - Seizures
  - Intracerebral hemorrhage

Metabolic
  - Hypokalemia
  - Hyperglycemia

Other
  - Rhabdomyolysis
  - Muscle rigidity
  - Hyperthermia

Unique
  - Syndrome of inappropriate antidiuretic hormone associated with 3,4-methylenedioxymethamphetamine

BOX 149.3 Differential Diagnosis of Sympathomimetic Toxidrome

Toxic and Metabolic
  - Hyponatremia
  - Anticholinergics
  - Withdrawal syndromes

Endocrine
  - Hypoglycemia
  - Hyperthyroidism and thyrotoxicosis
  - Pheochromocytoma

Pulmonary and Cardiovascular
  - Hypoxia
  - Cerebrovascular accident
  - Intracranial hemorrhage
  - Subarachnoid hemorrhage, subdural hemorrhage, and epidural hemorrhage

Infectious and Inflammatory
  - Sepsis
  - Meningitis and encephalitis

Environmental
  - Heat stroke

Psychiatric
  - Psychosis not otherwise specified
  - Schizophrenia
  - Mania
infectious origin persists, a subsequent lumbar puncture should be obtained in the setting of a normal-appearing CT scan of the brain.

**EVALUATION (SPECIAL CONSIDERATIONS)**

**Body Packers**

The concealment of illicit substances within the gastrointestinal tract in large quantities requires close and careful evaluation. Individuals who take part in this trafficking, also known as body packers or “mules,” may be symptomatic or asymptomatic when they present to the ED. Those individuals with leaking or ruptured packets containing a sympathomimetic, often cocaine, need to be identified rapidly because they typically harbor enough drug to exceed multiple median lethal doses. Plain radiographs and oral contrast-enhanced CT scans of the abdomen have reasonable sensitivity in detecting packets; however, individuals already demonstrating signs and symptoms should receive an emergency surgical consultation with invasive removal of remaining packages. Body packers, if asymptomatic, require the same consideration, but they may necessitate a prolonged treatment course and monitoring.

**Methylxanthines or Beta-Agonists**

Patients who present with signs and symptoms consistent with methylxanthine or beta-agonist exposure should have their serum theophylline levels tested. At-risk populations include individuals with a history of reactive airway disease and those with tachycardia, hypotension, widened pulse pressure, nausea, vomiting, tremor, hypokalemia, or hyperglycemia.

---

**TREATMENT**

All patients should have vital signs recorded and continuously monitored, with close attention paid to core temperature. In addition, supplemental oxygen should be administered because of the increased metabolic demand.

Patients who have ingested sympathomimetics should receive activated charcoal if it can be safely administered. Individuals who overdose on theophylline should be considered for aggressive decontamination with multiple-dose activated charcoal because it has been shown to enhance elimination of theophylline from gastrointestinal circulation.

Because of the large drug burden and the risk of packet leakage or rupture in body packers or “mules,” whole-bowel irrigation (WBI) can be used as first-line treatment in the asymptomatic patient. WBI can hasten the passage of packets through the gastrointestinal tract. This decontamination modality requires stringent dosing, averaging 2 L/hour of polyethylene glycol orally for an adult patient, with dose adjustments for the pediatric population. Most patients are unable to maintain this rate voluntarily and therefore require nasogastric tube placement. WBI is not without complications. Thus, consulting a toxicologist to discuss treatment is beneficial.

The focus of therapy should be reducing morbidity and mortality by controlling psychomotor agitation or seizures and correcting hyperthermia. Animal studies showed benzodiazepines to be the most effective treatment.

The psychomotor agitation and seizures can result in severe rhabdomyolysis, which, if unrecognized, may result in renal insufficiency or failure. A combination of hyperthermia,
metabolic acidosis, and rhabdomyolysis can produce a vicious cycle, which should be recognized and treated immediately.

Mortality related to cocaine use has been associated with an elevation in core and ambient temperature. An ice bath that covers the largest surface area can quickly and effectively reduce core temperature. Other common modalities employed include mist and fan, as well as strategic anatomic application of ice packs (i.e., axilla and groin).

Most patients present with hypovolemia secondary to increased metabolic demand, diaphoresis, and psychomotor agitation. Fluid resuscitation to the point of euvolemia is recommended.

**SPECIAL CONSIDERATIONS**

**Beta-Agonists**
For known beta-agonist exposures, it would seem logical to administer a β-adrenergic receptor antagonist. However, patients usually overdose on their own medications. In asthmatic patients, administration of a β-receptor antagonist is contraindicated and potentially dangerous. However, if no contraindication to beta-blocker use exists, careful administration and titration of an agent, such as esmolol and metoprolol, can be performed.

**Methylxanthines**
Although they are not as common as in the past, theophylline overdoses can be treated aggressively with multiple-dose activated charcoal to enhance elimination, as well as hemoperfusion or hemodialysis. Tachydysrhythmias associated with theophylline overdose can be suppressed with β₁-selective antagonists. As mentioned previously, however, these patients usually overdose on their own medications, thus making the use of β-receptor antagonists precarious.

**Cocaine**
Multiple agents are available to treat cocaine’s unique properties of vasoconstriction and sodium channel blockade. The first-line agent for treatment of cocaine toxicity is a benzodiazepine; however, some patients do not respond to this therapy. Ongoing vasoconstriction or vasospasm can be treated with an α-adrenergic receptor antagonist, such as phenolamine. In the setting of cocaine-associated acute coronary syndrome, β-adrenergic blockade is contraindicated despite the mortality benefit observed in patients with acute coronary syndrome unassociated with cocaine. The use of beta-blockers in cocaine toxicity is contraindicated because once the β-adrenergic receptor is blocked, these individuals suffer from unopposed α-adrenergic stimulation, thus worsening their clinical course. Even in the setting of suspected pure β-adrenergic agonist exposure, β-adrenergic blockade is rarely recommended because the underlying substrate usually depends on β-receptor agonism (i.e., asthmatic patients who overdose on albuterol).

A unique property of cocaine is its ability to block myocardial sodium channels. This manifests as wide complex tachydysrhythmia resulting from sodium channel blockade. These electrophysiologic effects are indistinguishable from those of other class I antidysrhythmics and require immediate attention and reversal with either sodium bicarbonate or lidocaine.

Symptomatic cocaine body packers require urgent surgical removal of residual packets. In some instances, body packers are not symptomatic, and WBI can be initiated. In the event that packets cause a mechanical obstruction, endoscopic removal is a successful treatment modality.

**3,4-Methylenedioxymethamphetamine**
MDMA-associated SIADH usually responds to conservative fluid restriction. However, patients with severe CNS manifestations should receive hypertonic saline solution to correct a portion of the metabolic imbalance rapidly.

**Vasopressors**
Epinephrine and norepinephrine can extravasate within tissue compartments during infusion, as well as from unintentional exposures related to autoinjectors. Warm compresses should be placed topically for mild cases, and nitroglycerin paste can be added topically to generate vasodilation. For severe cases, intradermal phentolamine may be introduced within the exposed tissue.

---

**TIPS AND TRICKS**

- The clinician should avoid neuroleptics (i.e., haloperidol) or antihistamines (i.e., diphenhydramine) to control the psychomotor agitation and psychosis associated with sympathomimetic overdose. Because neuroleptics have anticholinergic properties, decrease seizure thresholds, and increase QT intervals, these agents are a poor choice to achieve sedation. Anticholinergic toxicity is within the diagnostic consideration of the undifferentiated agitated delirium, such that administration of an anticholinergic agent may be additive to potential morbidity. Benzodiazepines are the preferred choice for sedation.
- The only situation in which fluid resuscitation should not be initiated before laboratory evaluation is in the individual suspected to have syndrome of inappropriate antidiuretic hormone from 3,4-methylenedioxymethamphetamine use.
- Because of persistent tachycardia and extrapolating data from acute coronary syndromes, emergency physicians often feel compelled to rate-control these patients with β-adrenergic receptor antagonists. Potential unopposed α-adrenergic agonism may lead to a hypertensive crisis, and these agents therefore should be avoided in the undifferentiated sympathomimetic toxidrome.
- Amiodarone is listed as a first-line agent in the treatment of wide complex tachycardia. Concern exists about the intrinsic β-adrenergic receptor antagonist properties of amiodarone, for the reasons stated. Amiodarone should not be used in the setting of cocaine toxicity because of this theoretical risk.

**DISPOSITION**

The length of stay and disposition depend on the duration of action of the sympathomimetic, which is highly variable. Recreationally smoked or insufflated cocaine has a short duration of action, usually lasting no more than 4 hours, and patients can normally be discharged from the ED. Side effects such as
rhabdomyolysis, heat stroke, or end-organ injury require ongoing monitoring and treatment. Prolonged effects may be seen in individuals who are body packers and in patients who use long-acting agents such as clenbuterol, a potent β-adrenergic receptor agonist. These individuals require admission and prolonged treatment.

The evaluation and treatment of cocaine-associated chest pain have evolved and have regional variation. A short observation period with serial ECGs and serial cardiac-specific markers performed 6 to 8 hours apart can be used to exclude cocaine-associated myocardial infarction. Despite excluding the diagnosis of myocardial infarction, all patients should have urgent outpatient evaluation for coronary artery disease and drug abuse counseling.

**SUGGESTED READINGS**

**REFERENCES**

References can be found on Expert Consult @ www.expertconsult.com.
REFERENCES

(although perhaps less frequently suspected) in white, employed, and insured individuals as in patients who are non-white, unemployed, or homeless. In the last 2 decades, first-time drug use has become more common among adolescents, and the variety of drugs used has exploded. Drug use is no longer limited to what can be identified on a standard hospital toxicology screen, and many of the drugs people abuse to become high are not illegal, such as cough and cold products and prescription medications. The rampant growth of drug use is likely linked to the proliferation of the Internet and the wide availability of unregulated partisan drug sites that enable potential users to learn about drugs, to order the raw ingredients and supplies to manufacture their own drugs, or simply to purchase drugs online in the safety of their own homes.

**PATHOPHYSIOLOGY**

The drugs available for recreational abuse are countless and are constantly evolving. In the past, recreational drugs were categorized, for the purposes of discussion, identification, and treatment, somewhat arbitrarily on the basis of structural class, predominant biochemical or neurotransmitter activity (e.g., dopaminergic versus serotonergic versus gamma-aminobutyric acid [GABA]–ergic), or expected clinical effect (e.g., hallucinogen versus stimulant versus entactogen). In reality, most drugs exhibit multiple biochemical effects of varying intensity that are not limited to a particular structural class, and clinical findings vary widely among different individuals even when these persons are exposed to the same drug. Physicians now recognize that clinical variability depends not only on the specific type of drug but also on the dose used, the form of drug (e.g., crystal versus powder versus liquid), the purity of the drug, the route of delivery (e.g., intranasal versus ingestion versus injection), the concomitant use of coingestants, individual genetic polymorphisms, and individual biochemical and physiologic adaptations from long-term exposure.

Most recreational drugs are highly lipophilic and easily cross the blood-brain barrier, so most result in some euphoria; otherwise, patients would have little reason to abuse them. Although the exact mechanisms are still incompletely understood, modulation of central dopaminergic activity, which is responsible for pleasure seeking and reward reinforcement, is an important factor in the euphoric response and the development of drug addiction. Recreational drugs also affect, to

---

**KEY POINTS**

- The most common chief complaint when patients have hallucinogenic intoxication is altered mental status.
- Optimal treatment depends on symptom-based (rather than drug-based) diagnostic strategies and interventions.
- An elevated temperature is the most important prognostic sign of poor outcome.
- Most new drugs cannot be identified with hospital-based blood or urine tests, and results of urine drug screens should never be considered diagnostic.
- Treatment for drug-induced hypertension should involve generous doses of benzodiazepines before antihypertensive agents are considered.
- Substance abuse counseling and referral are required for all patients before discharge.

**EPIDEMIOLOGY**

Recreational abuse of hallucinogens and other drugs is common among patients in the emergency department (ED) and is directly responsible for many ED visits. Although the exact prevalence of drug abuse in patients in the ED is unknown because so much drug abuse goes undetected, various surveillance studies all indicate that ED visits related to drug use continue to rise yearly.

Patients who present to an ED immediately after using a drug do so for various reasons: an unfavorable or unanticipated reaction to the drug, an unintentional overdose, a traumatic injury, altered mental status, or suicidal and other dangerous behavior. In addition to the acute complications directly related to drug use, many cardiovascular, neurologic, infectious, psychiatric, and social health problems treated in the ED are linked to chronic drug abuse. Because drug abuse is often not declared by the patient at the time of arrival, recognition and optimal treatment require vigilance from the emergency physician, as well as attention to historical, clinical, and laboratory clues.

Recreational drug use today knows no demographic, age, or socioeconomic boundaries. Drug use is just as common
variable extents, peripheral and central norepinephrine, serotonin (5-HT), N-methyl-D aspartate (NMDA), and GABA activity.

**PRESENTING SIGNS AND SYMPTOMS**

The most common presenting feature in all patients with recreational drug use is some degree of altered mental status. It may range from seemingly benign giddiness to life-threatening agitation or obtundation. Drug-associated altered mental status may be associated with any kind of vital sign abnormalities or evidence of end-organ damage. Cardiovascular, neurologic, infectious, and psychiatric complaints are also common (Table 150.1). Because the predominant drugs seen in a particular ED vary depending on local geographic preferences and because the types of drugs abused change far more quickly than published medical literature can keep up with, optimal treatment depends on symptom-based (rather than drug-based) diagnostic strategies and interventions.

The following paragraphs discuss some of the more common drugs of abuse historically prevalent in most EDs. Identifying previously undetected drug abuse requires some familiarity with these common drugs and the street slang associated with them (Table 150.2).

### AMPHETAMINE

Commonly referred to as “crank” or “speed,” amphetamine is a specific drug first synthesized in 1887 and initially marketed as a decongestant and appetite suppressant. Many other drugs with a similar chemical structure, such as methylenedioxymethamphetamine (MDMA) and methamphetamine, are collectively called *amphetamines*, even though their clinical effects vary. More precisely, these drugs are all derived from

---

**PRIORITY ACTIONS**

**Altered Mental Status, Seizures, or Behavioral Changes?**
- Does the patient have a central nervous system infection, infarction, lesion, or mass?
- Consider brain imaging and lumbar puncture if neurologic status is inconsistent with intoxication.

**Apnea or Depressed Respirations?**
- Consider treatment with naloxone to reverse potential narcosis or dextrose and thiamine for hypoglycemia.
- Intubation may be needed for persistent hypoxia or an inability to protect the airway.

**Chest Pain?**
- Evaluate the patient for myocardial ischemia with electrocardiography, telemetry, and cardiac enzyme measurements.

**Fever or Hyperthermia?**
- Does the patient have any history or evidence of intravenous drug use?
- Consider evaluation for endocarditis or epidural abscess.
- Consider active cooling and liberal benzodiazepine treatment if sympathomimetic intoxication is suspected.
stimulation, medical complications such as acute coronary syndrome, seizures, cerebral vascular accidents, intracranial hemorrhage, renal failure, and rhabdomyolysis are common.12,13 Cocaine washout syndrome occurs after cocaine binging. Affected patients typically have a depressed mental status ranging from lethargy to obtundation that lasts up to 24 hours until depleted neurotransmitters are regenerated.

DEXTROMETHORPHAN
Also known as DXM, dextromethorphan is a common antitussive agent found in over-the-counter and prescription medications in liquid or tablet form. It is a synthetic analogue of codeine but does not have the same analgesic effect because its activity is primarily at NMDA and 5-HT receptors.7,10 Hallucinations are commonly reported, and in addition to some opioid features, patients may exhibit ataxia, slurred speech, nystagmus, tachycardia, hypertension, dystonia, and seizures.

GAMMA-HYDROXYBUTYRATE
Gamma-hydroxybutyrate (GHB), also known as “Georgia Home Boy” and “Liquid G,” has been variously used as an exercise supplement, for treatment of narcolepsy, for obtaining chemical submission of victims, and for euphoria. GHB works primarily at GABA receptors and the still poorly defined GHB receptor.14,15 The analogues gamma-butyrolactone (GBL), 1,4-butanediol (1,4-BD), gamma-hydroxyvalerate methyl-GHB (GHV), and gammavalerolactone 4-pentanolide (GVL) work similarly because they are all converted to GHB through various pathways after ingestion. GHB easily crosses the blood-brain barrier and produces loss of consciousness within 15 to 30 minutes of ingestion. Bradycardia, vomiting, myoclonic jerks, and hypothermia are commonly associated. Duration of unconsciousness lasts 2 to 6 hours in most cases.16

JIMSONWEED
Jimsonweed is the common name of plants in the Datura genera. Intoxication with jimsonweed was first reported in 1676. The plants grow throughout the United States, and all parts of it—the fruit, flower, and seeds—can be abused for their hallucinogenic properties. Because these plants contain the alkaloids atropine, scopoline, and hyoscyamine, clinical effects associated with jimsonweed hallucinations include anticholinergic findings such as dilated pupils, dry mouth, warm and flushed skin, diminished bowel sounds, and urinary retention. Cardiovascular instability, hypothermia, and seizures have been reported after large ingestions.17

KETAMINE
Also known as “Special K,” “Kitty Valium,” and “Kiddie Valium,” ketamine is a structural and functional analogue of phencyclidine (PCP) and also works primarily at NMDA receptors.18 Ketamine can be ingested or injected. Patients with ketamine abuse have symptoms similar to those of PCP intoxication, including rotatory nystagmus, excessive salivation, muscle rigidity, tachycardia, and hypertension, although the effects tend to last a shorter time.5,18

LSD
D-Lysergic acid diethylamide (LSD) was first synthesized in 1938. It is available in tablets, liquid, powder, and gelatin a phenylethylamine core and should be collectively called phenylethylamines (MDMA and methamphetamine are discussed separately). Amphetamines are currently available as tablets in the form of a prescription (e.g., methylphenidate [Ritalin], proprietary mixture of amphetamine salts [Adderall]) or in a designer form produced in a clandestine laboratory.11 The onset of symptoms occurs within 15 minutes of ingestion, and symptoms last 6 to 12 hours. The effects are primarily stimulant because of amphetamine’s activity at peripheral and central norepinephrine and dopamine sites.3 Varying levels of tachycardia, hypertension, hyperthermia, diaphoresis, and agitation are commonly seen in the ED in a patient who has ingested an amphetamine, and cardiac and central nervous system (CNS) complications have been frequently reported.

COCAINE
Cocaine is also discussed in Chapter 149, Sympathomimetics. Derived from Erythroxylon coca, a shrub indigenous to South America, cocaine is well absorbed by any mucosal route and thus is abused when snorted, smoked (crack), or injected intravenously. Effects typically occur within 5 to 15 minutes and last 1 to 4 hours. The effects are primarily stimulant and are related to its effects on the sympathetic nervous system: increasing the release of norepinephrine and blocking its reuptake.7,12 Concomitant use of cocaine with alcohol results in increasing the release of norepinephrine and blocking its reuptake.3,12 Concomitant use of cocaine with alcohol results in

Cocaine is also discussed in Chapter 149, Sympathomimetics. Derived from Erythroxylon coca, a shrub indigenous to South America, cocaine is well absorbed by any mucosal route and thus is abused when snorted, smoked (crack), or injected intravenously. Effects typically occur within 5 to 15 minutes and last 1 to 4 hours. The effects are primarily stimulant and are related to its effects on the sympathetic nervous system: increasing the release of norepinephrine and blocking its reuptake. Concomitant use of cocaine with alcohol results in increasing the release of norepinephrine and blocking its reuptake.3,12 Concomitant use of cocaine with alcohol results in
squares, although the most commonly abused form of LSD is “blotter” acid (sheets of paper sprayed with LSD, dried, and then perforated into small squares). Effects occur within 30 minutes, can last for 16 to 24 hours, and cause powerful hallucinations from serotonergic (5-HT) and dopaminergic activity. Time is distorted, and visual hallucinations of bright colors are common. Tachycardia, hypertension, anxiety, and paranoia are frequently seen in patients who seek treatment in the ED as a result of LSD use. Significant medical complications are uncommon.18

MARIJUANA
Also known as “grass,” “weed,” or “pot,” marijuana is considered the most commonly used illegal substance in the United States. Marijuana is primarily smoked; its effects occur within 15 minutes and can last up to 4 hours. The psychoactive substance, delta-9-tetrahydrocannabinol, is derived from the plant Cannabis sativa.3 Clinical effects are variable and seem to occur as a result of cannabinoid receptor activity in the brain. Inappropriate laughter, excessive hunger, anxiety, paranoia, ataxia, and tachycardia are commonly seen. Various synthetic cannabinoids (known by names such as Spice, K2, and Sky Incense) have become available to users in herb shops.19 The duration of symptoms has reportedly been longer than for naturally growing marijuana. Medical complications associated with cannabinoid abuse alone are uncommon.

METHYLENEDIOXYMETHAMPHETAMINE
MDMA is better known as “Ecstasy,” “X,” “XTC,” and “ADAM” and is also discussed in Chapter 149, Sympathomimetics. It was first synthesized in 1914 but became wildly popular at rave parties and on college campuses in the 1980s and 1990s.13 Although it is a phenylethylamine like amphetamine, MDMA’s strong serotonergic activity has clinical effects that are primarily hallucinogenic and entactogenic.3 Variable tachycardia and hypertension can also occur from some stimulant activity. Hyperthermia has been reported as a complication of excessive dancing in warm rave clubs without adequate hydration, although other individual variabilities and drug contaminants are also likely responsible.3 Hyponatremia, another common occurrence with MDMA use, results from excessive ingestion of water or from MDMA-induced syndrome of inappropriate antidiuretic hormone secretion.

METHAMPHETAMINE
Also known as “meth,” “crystal,” “chicken feed,” and “white man’s crack,” methamphetamine has become one of the most popular drugs of abuse in the twenty-first century.20,21 Its popularity is related to its multiple forms (crystal, powder, liquid, and tablet), its ease of manufacture from decongestants such as pseudoephedrine, and its low street cost (less than one third the cost of cocaine). Methamphetamine has strong norepinephrine activity and, of all the phenylethylamines, is the most quickly addictive because of its strong dopaminergic action.1 It can be ingested, snorted, smoked, injected, or administered rectally. Clinical findings are similar to those associated with other stimulant intoxications, and acute coronary syndrome and cerebrovascular accident have been reported. Other hallmark features of methamphetamine are poor dentition, known as “meth mouth,” from poor hygiene and bruxism and dermatologic lesions called “crank bugs” or “meth mites,” from compulsive scratching that is likely delusional in origin.

OPIOIDS
Naturally occurring or synthetic drugs with opium-like or morphine-like activity have always been popular. The poppy plant, Papaver somniferum, is the source of opium and contains the alkaloids morphine and codeine. Opioid effects are primarily modulated throughout the peripheral and CNS by interacting at three main opioid receptors: μ, κ, and δ.1 The classic opioid toxidrome comprises CNS depression, respiratory depression, and miosis, although the intensity of each of those features varies among the different synthetic opioids. Prehospital deaths typically occur from untreated apnea.22 Abuse of prescription opioids continues to rise, especially abuse of methadone and fentanyl patches. Data indicate that the abuse of combination acetaminophen-opioid analgesics is directly related to rising rates of acetaminophen-induced hepatic failure.23

OTHER NATURAL PRODUCTS
Naturally found herbs, plants, and other related products have become especially popular during the Internet drug era. Adolescents and young adults have been reported to use morning glory seeds for LSD-like effects, nutmeg for myristicin-associated hallucinogenic effects, and the plant Salvia divinorum (known also as “Sally D” and “Diviner’s mint”) for κ-opioid–mediated hallucinogenic effects.24 Naturally occurring recreational drugs are popular because they are considered “naturally” safe and can be used in various ways by users, including ingestion, insufflation, smoking, injection, and even tea consumption. Effects typically last 2 to 6 hours, and medical complications are uncommon, although long-term effects are still unknown.

PRESCRIPTION MEDICATIONS
Nonmedical abuse of prescription drugs has been identified as a national epidemic. In 2005, nearly 15 million U.S. residents abused prescription drugs, including prescribed opioids, sedatives, antidepressants, and stimulants.1 One of the reasons for the rapid rise of prescription drug abuse is the perception that these agents are safer than traditional street drugs. The growing rates of prescriptions written for analgesia, for mood disorders, and for attention-deficit hyperactivity disorder have resulted in experimentation with easily available tablets by the family members or friends of the person for whom the agents were prescribed.9,11

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING
Drug intoxication should always be considered in the differential diagnosis of any patient presenting to the ED with altered mental status. Infectious, metabolic, neurologic, endocrinologic, structural, and psychogenic causes should also be considered in the evaluation of the patient with suspected drug intoxication. The history of events immediately preceding onset of symptoms, if available to the clinician from the patient or witnesses, is most helpful in narrowing the diagnosis.

Asymptomatic patients with drug intoxication who have normal vital signs and normal physical findings do not require diagnostic testing. Patients with mild symptoms should undergo rapid blood glucose measurement because

</tbody>
</table>

hypoglycemia or hyperglycemia may cause altered mental status. Ethanol measurement should be obtained if alcohol is suspected as a coingestant or to exclude alcohol ingestion as a cause of altered mental status. Patients who are agitated, hyperthermic, or seizing or were found after prolonged obtundation are all at risk for the development of rhabdomyolysis and should be evaluated with a basic metabolic profile, renal function tests, measurements of calcium, phosphorus, total creatine phosphokinase levels, and urinalysis.5

Electrocardiography should be performed in all patients with tachycardia or bradycardia, and telemetry monitoring should be instituted. Patients with altered mental status inconsistent with their reported drug use, new-onset seizure, or signs of traumatic injury or suspected trauma should be evaluated with computed tomography of the head (Table 150.3).

The toxicology drug screen has limited utility in the ED setting and should be used only for a patient in whom mental status is altered and the diagnosis is not clear. Several studies confirm that a careful patient history and attention to clinical signs make toxicology screens unnecessary in most cases of drug intoxication.26,27 For example, a patient with depressed respirations, depressed mental status, and pinpoint pupils consistent with an opioid toxidrome who completely awakens after the administration of naloxone does not need a costly urine drug screen to confirm opioid toxicity. Furthermore, waiting for the results of a urine drug screen before administering lifesaving naloxone is impractical in cases of severe intoxication. The drug screens available in most hospitals have a limited panel, and many of the nontraditional, emerging, and Web-based drugs (new drugs, including prescription medications and club drugs) cannot be detected by such hospital screens.5

Toxicology screens are limited by what they cannot detect, and they can yield false-positive results related to contaminants. For example, over-the-counter decongestants used appropriately for an upper respiratory infection can yield a falsely positive amphetamine screen result, and quinolones can cause falsely positive opioid screen results.28 Finally, urine drug screen results are not forensically defensible because most hospitals analyze urine with only one laboratory technique, and the chain of custody is not enforced from patient to laboratory (Box 150.1).

**RED FLAGS**

- An elevated temperature is prognostic of poor outcomes.
- Focal neurologic findings are indicative of seizure activity or intracranial lesion.
- Rhabdomyolysis can occur in cases of agitation or prolonged obtundation.
- Renal insufficiency or creatine phosphokinase elevation requires adequate fluid resuscitation to prevent renal failure.

**DOCUMENTATION**

- Amount ingested?
- Route of ingestion (oral, intravenous, subcutaneous, dermal, sublingual, rectal)?
- Time of ingestion?
- Coingestants?
- History of trauma?
- Previous emergency department visits for drug abuse?
- Previous detoxification or other treatment programs?
- Referral for counseling, treatment program, or detoxification

**TREATMENT**

Because the clinical presentation of drug intoxication varies widely, optimal treatment must be symptom based. Attempts to confirm identification of the drug should be postponed until the patient is stabilized. As with any patient in the ED,
attention to airway management is the top priority in all patients with drug intoxication. Obtunded patients with a poor respiratory effort should receive either naloxone, in an effort to reverse potential narcosis, or dextrose and thiamine for hypoglycemia. Intubation should be performed for persistent hypoxemia or the inability to protect a patient’s airway. Intravenous fluids should be administered to treat hypotension. Dysrhythmias should be treated according to standard Advanced Cardiac Life Support guidelines. A thorough examination must be completed to exclude concomitant traumatic injuries that require emergency management.

Patients who are agitated or difficult to control should receive liberal benzodiazepine treatment for their own safety, as well as staff safety, and to ensure a complete examination. Butyrophenones, such as haloperidol, may be considered if benzodiazepines do not successfully control the difficult patient. Although physical restraints may be needed temporarily for patient and staff safety, chemical sedation with benzodiazepines must be given top priority, to minimize the duration of potentially harmful physical restraints.

Drug-induced hypertension and tachycardia should also be treated first with benzodiazepines because these clinical findings primarily result from direct stimulant effects and are effectively managed in most cases with liberal benzodiazepine sedation. Short-acting antihypertensive agents with minimal beta-blocker activity may be considered only after sufficient doses of benzodiazepines have been administered.

Hyperthermia must be aggressively treated with external cooling measures and, if the patient is agitated, with liberal benzodiazepine therapy as well. Close monitoring of the patient’s core temperature is critical because an elevated temperature is the only vital sign abnormality consistently associated with poor outcomes in cases of drug intoxication.

Renal insufficiency or an elevated creatine phosphokinase value requires adequate fluid resuscitation. Drug-induced rhabdomyolysis results in renal failure and hemodialysis in 10% of patients hospitalized for drug intoxication and associated rhabdomyolysis.

FOLLOW-UP, NEXT STEPS OF CARE, AND PATIENT EDUCATION

Most patients with single-drug intoxication who have improved can be safely discharged after 4 to 6 hours of ED observation. In patients with multiple drug ingestion, prolonged clinical effects of long-acting agents such as methadone, or medical complications, admission to a monitored hospital bed is appropriate. Attention to signs of withdrawal is important before such a patient is discharged. Whether being discharged from the ED or from an inpatient bed, all patients with drug intoxication require substance abuse counseling and referral for support groups, detoxification, and other outpatient treatment.

Toxic Alcohols

Mark B. Mycyk

KEY POINTS

- Toxic alcohol poisoning may initially be mistaken for simple inebriation.
- Untreated ethylene glycol poisoning may result in renal failure.
- Untreated methanol poisoning may result in blindness.
- Acidosis from ethylene glycol or methanol may not be evident until several hours after exposure.
- An osmol gap may not be evident in patients whose presentation to the emergency department is delayed, and these patients benefit from early dialysis.
- An osmol gap measurement is only a screening test and is never diagnostic like a quantitative alcohol measurement.
- Isopropanol poisoning classically results in an elevated osmol gap without significant acidosis.
- Treatment with ethanol or fomepizole should be considered in cases of a witnessed ingestion of a toxic alcohol, when such an ingestion is highly suspected from the history, in the presence of an enlarged osmol gap alone with appropriate clinical suspicion, in the patient with both an enlarged osmol gap and anion gap acidosis, or when the serum concentration of a toxic alcohol exceeds 20 mg/dL.
- Early alcohol dehydrogenase inhibition minimizes metabolism of the toxic alcohol to organic toxic acids and reduces alcohol-specific complications.

EPIDEMIOLOGY

Except for ethanol, no other alcohols are fit for human consumption, and they are properly termed toxic alcohols. Ethylene glycol, methanol, and isopropanol are the most common toxic alcohols associated with human poisoning. Less commonly reported but still clinically important toxic alcohols are propylene glycol, diethylene glycol, and other glycol ethers. Unintentional ingestion from a mislabeled or contaminated container occurs commonly in children, whereas intentional ingestion of a toxic alcohol as an ethanol substitute or for self-harm occurs more commonly in adults. If untreated, toxic alcohol poisoning can result in metabolic acidosis, renal failure, blindness, central nervous system (CNS) injury, pulmonary edema, or death.

Ethylene glycol is present in antifreeze solutions, deicing solutions, foam stabilizers, and chemical solvents. Methanol is a component of windshield-washing solutions, gas-line antifreeze solutions, solvents, and brake cleaners. Isopropanol is found in rubbing alcohol, aerosols, and other cosmetic products. Propylene glycol is commonly found as a diluent in parenteral medications such as phenytoin, diazepam, and lorazepam. The other toxic glycols can be found in various household and industrial cleaners, paints, resins, and solvents.

More than 35,000 toxic alcohol exposures are reported yearly to the American Association of Poison Control Centers. Most cases are individual poisonings. However, contamination of beverages or pharmaceutical products has resulted in epidemic poisonings, including two significant outbreaks, in India and in Haiti in the 1990s, from diethylene glycol that affected hundreds of victims.

Definitive laboratory confirmation of toxic alcohol poisoning is usually not immediately available to the emergency physician. However, early recognition of poisoning and emergency department (ED)–initiated interventions significantly improve patient outcomes and reduce the occurrence of alcohol-specific complications.

PATHOPHYSIOLOGY

Most toxic alcohol poisonings occur by oral ingestion. Significant methanol poisoning has also been reported to occur by inhalation of brake cleaning products, and isopropanol poisoning has occurred through transcutaneous absorption in children treated for fevers at home with rubbing alcohol baths. Complete absorption is rapid by any route, each alcohol has a small volume of distribution (0.5 to 0.8 L/kg), and metabolism to toxic organic by-products occurs through hepatic alcohol dehydrogenase (ADH) (Figs. 151.1 and 151.2).

Toxicity from the parent products is limited to local mucous membrane irritation and CNS depression. The term toxic is specifically related to the production of different toxic by-products (oxalic acid and formic acid) by each of these alcohols. Ethylene glycol metabolism results in renal failure from deposition of oxalic acid in renal tubules. Methanol...
metabolism to formic acid results in blindness from direct injury to the retinal and optic nerves.3

Because the rate of metabolism through ADH varies by alcohol type and by individual variability in cytochrome P-450 genetic expression, clinical onset of worrisome symptoms can be delayed by 1 to 36 hours.2,3 Furthermore, the concomitant presence of ethanol may delay metabolism to the toxic by-products because ethanol has a higher affinity for ADH than the toxic alcohols and competitively inhibits metabolism of these alcohols to toxic by-products until the serum ethanol concentration drops to less than 100 mg/dL.

Isopropanol is unlike ethylene glycol and methanol in that it is not metabolized to an organic acid. Instead, it is metabolized to acetone, an osmotically active CNS depressant, which leads to profound inebriation (Fig. 151.3).8

### PRESENTING SIGNS AND SYMPTOMS

**CLASSIC OR TYPICAL**

Most patients poisoned with a toxic alcohol demonstrate some level of CNS depression consistent with inebriation (Table 151.1). Patients who arrive in the ED either shortly after a large ingestion or later after an ingestion, such that systemic accumulation of toxic metabolites has occurred, may be obtunded on presentation or may become obtunded during ED evaluation. The level of inebriation does not correlate with peak serum concentrations of the parent product or the accumulation of metabolic by-products.

Other clinical findings range from mild to life-threatening, depending on the type of alcohol and the dose consumed. Because the clinical toxicity from these alcohols results from the accumulation of specific toxic metabolites, some patients may appear relatively asymptomatic before the manifestation

</table>
of significant symptoms. Hypotension with reflex tachycardia is common in significant ingestions because of the vasodilatory effects common to all alcohols. In patients with ethylene glycol or methanol poisoning, routine laboratory analysis classically shows anion gap metabolic acidosis and an enlarged osmol gap. Patients with isopropanol poisoning typically have only an enlarged osmol gap, because isopropanol is not metabolized to any organic acids. Patients poisoned with the other toxic alcohols, such as diethylene glycol or butyl ethers from household cleaning products, have acidosis of varying degrees and inconsistently demonstrate an enlarged osmol gap.

**TYPICAL VARIATIONS**

Ethylene glycol poisoning that progresses to significant organic acid accumulation can cause Kussmaul respirations from severe acidosis, cerebral edema, and seizures. Multiple reports have described various self-limited cranial nerve palsies associated with ethylene glycol. Tubular necrosis from local oxalate deposition and renal failure are common. Because oxalic acid precipitates calcium, dysrhythmias and tetanic spasms secondary to hypocalcemia have been reported.

Metabolism of methanol to formic acid gives rise primarily to neurologic and ophthalmologic findings. Patients who are not obtunded may have severe headache, vomiting, dizziness, and amnesia. Cerebral edema, necrosis, and infarcts have been identified on intracranial imaging. Visual disturbances range from simple blurring to “snowstorm” vision to blindness. Worrisome eye findings include sluggish nonreactive pupils, papilledema, a hyperemic optic disk, and retinal edema.

Isopropanol ingestion is associated with a fruity breath odor from acetone accumulation and CNS depression that is reportedly two to four times more profound than would be expected from an equivalent dose of ethanol. Vomiting and hemorrhagic gastritis have also been reported in patients with isopropanol ingestion.

Propylene glycol is metabolized to lactic acid. This poisoning typically occurs iatrogenically from the diluent present in parenteral medications such as phenytoin and various benzodiazepines. Accumulated lactate in these cases has been associated with profound hypotension and cardiac dysrhythmias.

Diethylene glycol and the other butyl ethers have been associated with renal tubular necrosis, hepatitis, and pancreatitis.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis mnemonic “A CAT MUD PILES” should be used for any patient in whom ED evaluation demonstrates an anion gap acidosis (Box 151.1). Many of the possible conditions in the list can be easily excluded with a basic metabolic profile (e.g., uremia) and rapidly obtainable serum quantitative tests (e.g., salicylate). Although alcoholic ketoacidosis looks like toxic alcohol poisoning, it improves rapidly with only intravenous fluids and dextrose supplementation, whereas acidosis from a significant toxic alcohol exposure does not improve without antidotal treatment or enhanced elimination with hemodialysis, or both. In children, disorders of organic acid metabolism should be considered when poisoning is unlikely or has been excluded.

**BOX 151.1 Metabolic Acidosis with Elevated Anion Gap: “A CAT MUD PILES”**

- Alcoholic ketoacidosis
- Cyanide, carbon monoxide
- Alcohol
- Toluene
- Methanol, metformin
- Uremia
- Diabetic ketoacidosis
- Paraldehyde
- Iron, isoniazid
- Lactic acidosis
- Ethylene glycol
- Salicylates, strychnine

Laboratory testing in all patients with potential poisoning should include a basic metabolic profile to determine baseline renal function and acid-base status and to calculate the anion gap and osmol gap. In calculation of the osmol gap, the measured osmolality must be obtained at the same time as the basic metabolic panel (see “Facts and Formulas” box). The osmol gap value should be interpreted with caution because it is an imperfect screening test. The traditionally accepted normal value for an osmol gap is less than 10 mOsm/L. Unfortunately, an individual’s normal gap may range between −14 and +10 mOsm/L, so the osmol gap by itself is imperfect and not diagnostic.

**FACTS AND FORMULAS**

\[
S_I = \frac{S_V}{B_S} 
\]

**Anion Gap**

- Anion gap = \(Na^+ + (HCO_3^- + Cl^-)\) [normal anion gap = 8-12 mEq/L]
- Osmol gap = measured osmols − calculated osmols
- Calculated osmols = \((2Na^+ + BUN/2.8 + \text{glucose/18} + \text{ethanol/4.6})\) [normal osmol gap < 10 mEq/L]

**BUN**, Blood urea nitrogen; \(HCO_3^−\), bicarbonate.

Additional serum tests include the following: (1) an ethanol measurement, to enable accurate calculation of the osmol gap and determine the need for additional ADH inhibition; and (2) measurement of the calcium level, which can be depressed in cases of ethylene glycol poisoning and may lead to prolonged QT, cardiac dysrhythmias, and tetany. Arterial blood gas measurements should also be obtained to determine the level of acidosis.

Urinalysis should be performed to look for crystals: monohydrate (spindle-like) or dihydrate (envelope-shaped) crystals are present in 50% to 60% of cases of ethylene glycol poisoning and suggest significant poisoning. However, the absence of these crystals does not reliably exclude poisoning. Some authorities have suggested examining the urine under a Wood
Toxic Alcohols

Although ED clinical decisions depend mostly on clinical suspicion and interpretation of imperfect laboratory data such as the anion gap, osmol gap, and urinalysis, cases of suspected toxic alcohol poisoning require that measurements of serum concentrations of ethylene glycol, methanol, and isopropanol be ordered as soon as possible. These measurements are the only definitive means of confirming the diagnosis and guiding duration of both antidotal therapy and hemodialysis. Unfortunately, most hospital laboratories are not equipped to run these tests and must send the specimens to an off-site reference laboratory. Except when the patient arrives with the appropriately labeled product that was ingested in hand, an early administration strategy is to order serum concentration measurements of all three of these alcohols because patients often do not know exactly what they ingested. Confirming the units of measure when these results are available is also important because different laboratories use different units, and management decisions may be significantly affected if test results are interpreted incorrectly. Serum concentration measurements for toxic alcohols other than ethylene glycol, methanol, and isopropanol are not routinely available; even if obtainable, test results do not guide management decisions.

In cases of ethylene glycol poisoning, a baseline electrocardiogram should also be obtained because of the potential for dysrhythmias resulting from hypocalcemia.

**TREATMENT**

Treatment decision making for the patient with toxic alcohol ingestion is easiest when the patient arrives with the ingested product in hand. Because this is an uncommon occurrence, definitive laboratory diagnosis is usually delayed by the need to send serum samples to off-site reference laboratories. ED treatment in these cases should not be delayed and must be based on a presumptive clinical diagnosis. Attention to the airway in cases of CNS depression should be the first priority. Intravenous fluids should be administered to treat hypotension and maintain renal perfusion in all cases of toxic alcohol poisoning.

Because alcohols are so rapidly absorbed, gastric emptying procedures are not necessary in patients with toxic alcohol poisoning.

In cases of suspected ethylene glycol or methanol poisoning, immediate ADH inhibition should be considered to block continued metabolism of the ethylene glycol to toxic acids. ADH inhibition is most effective when it is administered as early as possible after exposure and before significant acidosis develops. This treatment should be considered in cases of a witnessed ingestion, when this agent is highly suspected from the history, in the presence of an elevated osmol gap alone with appropriate clinical suspicion, in the patient with both an elevated osmol gap and anion gap acidosis, or when the serum concentration of a toxic alcohol exceeds 20 mg/dL.

ADH inhibition can be achieved with either ethanol or fomepizole. Until 1999, ethanol was the only clinically available antidote. Its affinity for ADH is higher than that of ethylene glycol and methanol, it is inexpensive, and it is readily available. An ethanol level of 100 mg/dL has been the accepted goal for ensuring complete ADH inhibition; after intravenous loading, ethanol levels must be checked regularly until the measured ethylene glycol or methanol concentration reaches below 5 mg/dL.
is lower than 20 mg/dL. An ethanol load may be administered orally or with an intravenous infusion (see “Facts and Formulas” box). Treatment difficulties associated with ethanol therapy include (1) iatrogenic inebriation of the patient and inability to monitor mental status, (2) potential occurrence of hypoglycemia in pediatric patients, and (3) difficulty maintaining a therapeutic level because of individual variability in ethanol metabolism and clearance.14

In cases of ethylene glycol poisoning, supplemental thiamine and pyridoxine should be administered to decrease the accumulation of oxalic acid (see “Facts and Formulas” box). In cases of methanol poisoning, supplemental folate should be given to enhance the elimination of formate by converting it to carbon dioxide and water. Although this approach is theoretically beneficial and has been found to be useful in some animal models, no human data demonstrate a clear benefit of cofactor administration.

Hemodialysis should be initiated in any patient with a significant ethylene glycol or methanol concentration and significant acidosis because it helps remove both the parent product and the resultant toxic acids.17,19 When a serum concentration is not immediately available, hemodialysis should be initiated in patients with clinical indicators of significant toxicity, such as pH less than 7.30 despite aggressive intravenous fluid resuscitation, creatinine concentration indicative of renal failure, or other electrolyte abnormalities unresponsive to conventional therapy.2,3,17 Hemodialysis should also be initiated soon after presentation in patients in whom ADH inhibition cannot be used because of antidote unavailability or a contraindication. Hemodialysis should also be considered to shorten the duration of antidote requirements and of hospitalization when acidosis has not occurred but the serum concentration of the toxic alcohol is extremely high.17,18 For example, the half-life of methanol has been reported to be as long as 54 hours in patients receiving ADH inhibition, and these patients may require several days of hospitalization and antidotal therapy if hemodialysis is not performed as well (Fig. 151.5).

Management of the other toxic alcohol poisonings requires aggressive supportive therapy, attention to the medical complications of acidosis, and hemodialysis only in the presence of significant renal insufficiency or other electrolyte abnormalities.13 Despite the similarity of its name to ethylene glycol, diethylene glycol does not produce oxalic acid, and any benefit from ADH inhibition in cases of diethylene glycol poisoning is uncertain.20

The use of fomepizole, which was approved by the U.S. Food and Drug Administration in 1999, is an easier form of ADH inhibition than the use of ethanol.14,16 Dosing is weight based, and unlike ethanol, fomepizole does not require a constant infusion (see “Facts and Formulas” box). Fomepizole is given every 12 hours in patients not receiving hemodialysis or every 4 hours in patients undergoing hemodialysis, it does not cause inebriation, and it does not require monitoring of serum levels to ascertain therapeutic efficacy.14 Fomepizole should not be given when ethanol concentrations are significantly elevated because ethanol works as an ADH inhibitor, and fomepizole’s higher affinity for ADH will prolong the half-life and the clinical inebriation by the ethanol. Fomepizole is not available in all hospitals because of its high cost.6

In cases of poisoning with any of the toxic alcohols, the addition of a sodium bicarbonate infusion should be initiated when acidosis is severe. Alkalization of serum is helpful in keeping acids in their ionic form. In patients with methanol poisoning, alkalinization of serum enhances the renal clearance of formate and may prevent formic acid from entering the CNS and affecting the optic nerves.

**TIPS AND TRICKS**

- Consult your local poison center: 800-222-1222.
- Refer to the Mountain schematic (see Fig. 151.4) to help interpret anion gap and osmol gap results.
- If long delays until definitive laboratory confirmation of the ingested substance are expected, consider repeating the basic metabolic profile or measure arterial blood gases.
- If alcohol dehydrogenase has not been blocked by fomepizole or ethanol, acidoses should worsen despite standard intravenous fluid resuscitation if ethylene glycol or methyl alcohol is present.
- Treatment difficulties associated with ethanol therapy are (1) iatrogenic inebriation and inability to monitor mental status, (2) potential occurrence of hypoglycemia in children, and (3) difficulty maintaining a therapeutic level because of individual variability in ethanol metabolism and clearance.
Suspected toxic alcohol poisoning

Airway management as needed, fluids for hypotension

Obtain chemistry panel, serum osmols, calcium, magnesium, ABG, UA for crystals, ethanol level, and toxic alcohol levels; consider salicylate and acetaminophen if coingestants possible

Anion gap acidemia? (anion gap may be normal if early arrival)

Yes

Confirm stat toxic alcohol level order (result may not be available), ECG, and initiate treatment

ADH blockade with ethanol or fomepizole (see “Facts and Formulas” box)

Sodium bicarbonate for severe acidosis (pH ≤ 7.2)

No

Osmol gap >10? (osmol gap may be normal if late arrival but patient should have had an anion gap)

Yes

No

Toxic alcohol level > 20 mg/dL?

Yes

Disposition based on any other factors/other potential diagnoses and need for psychiatric eval

No

Consult toxicology

Consult renal service to evaluate for hemodialysis

Cofactor supplementation (thiamine and pyridoxine for ethylene glycol and folate for methanol, see “Facts and Formulas” box)

Admit

Fig. 151.5 Treatment algorithm for toxic alcohol poisoning. *ABG*, Arterial blood gas measurements; *ADH*, alcohol dehydrogenase; *ECG*, electrocardiography; *UA*, urinalysis.

**DISPOSITION**

Patients without acidosis and with a toxic serum alcohol level less than 20 mg/dL may be discharged home if clinical findings and renal function are normal. Any patient receiving an ADH antidote must be admitted to the hospital until a definitive serum alcohol concentration is available. Patients with significant mental status depression or acidosis, patients who are receiving an intravenous ethanol infusion, or patients who need hemodialysis should be admitted to the intensive care unit because laboratory values must be checked frequently. Patients who arrive early after a significant ingestion may be considered for treatment in a setting other than the intensive care unit; these patients are given fomepizole therapy alone if no acidosis was detected before administration of the antidote.

In cases of intentional ingestion, appropriate psychiatric evaluation is warranted after the patient’s medical issues are treated. In cases of unintentional poisoning, especially in children, appropriate poison prevention counseling for all caregivers is required before discharge.21
**Documentation**

**History**
- Any history of psychiatric illness or earlier suicidal ingestions
- Time lapse since ingestion if known
- History of renal or cardiac disease or other illnesses that will exacerbate the complications of toxic alcohols

**Physical Examination**
- Does the patient look ill? Pale? Febrile? Mental status?
- Cardiac status (blood pressure, arrhythmias)?
- Respiratory and airway status
- Visual acuity if concern exists for methanol poisoning
- Urine output
- Repeated examination while patient is in the emergency department

**Studies**
- Laboratory tests and time the samples were obtained (serum osmol should be done at the same time as blood chemistry panel)
- Availability of toxic alcohol levels

**Medical Decision Making**
- Decision to begin treatment or delays
- Consultations and times that contacts were made

**Treatment**
- Availability of antidotes, time antidote was ordered, and any delays to treatment

**Patient Instructions**
- Document discussion with patient regarding diagnosis, warning signs, what to do, follow-up, and when to return
- With accidental ingestions in children, document poison prevention counseling

**Suggested Readings**

KEY POINTS

- Many hydrocarbons possess a characteristic odor similar to that of gasoline or lighter fluid. Solvents containing aldehyde or ketone groups smell sweet or fruity, and essential oils are characteristically pungent or aromatic. In acutely intoxicated patients, these odors are rarely missed.
- In assessing the patient with possible hydrocarbon exposure, important tasks are as follows:
  - Identification of the specific substance or substances
  - Quantification of the dose
  - Determination of the timing, duration, and course of exposure
  - Identification of the route or routes of exposure
  - Consultation or referral, or both, when indicated
- Many hydrocarbons are acutely cardiotoxic and have a propensity to induce tachyarrhythmias by sensitizing the myocardium to the arrhythmogenic effects of catecholamines.
- Gaseous or volatilized hydrocarbons are likely to cause toxicity through inhalation.
- Viscosity, surface tension, and volatility determine the aspiration potential and the risk of pulmonary toxicity.

EPIDEMIOLOGY

Adolescents 12 to 17 years old comprise the most likely age group to abuse volatile substances; U.S. eighth grade students have a 15% lifetime prevalence of this abuse. Volatile substance use should be suspected in this population. The habitual abuser of volatile substances may have paint stains or other telltale findings on the clothing or skin (see “Presenting Signs and Symptoms”).

Many hydrocarbons have a characteristic odor similar to that of gasoline or lighter fluid. Solvents containing aldehyde or ketone groups smell sweet or fruity. Essential oils are characteristically pungent or aromatic. In acutely intoxicated patients, these odors are rarely missed.

PATHOPHYSIOLOGY

A hydrocarbon is an organic compound composed mainly of carbon and hydrogen atoms. In modern society, these compounds are virtually everywhere. Hydrocarbons are so common in our society that exposures—even illnesses related to exposures—are not usually documented. Hydrocarbons derive most commonly from distillation and processing of petroleum, but many derive from plants (pine oil, essential oils), animal fats, and natural gas. An example is gasoline, which is a mixture of alkanes, alkenes, naphthenes, and aromatic hydrocarbons. Commercial gasoline contains hundreds—up to 1500—individual chemical species.

The term solvent is often used to refer to an organic solvent—typically a hydrocarbon mixture—that is used to dissolve other substances. Occupational literature often uses the terms solvent and hydrocarbon interchangeably. Organic solvents are common in industry, and workers may suffer dermal or inhalational exposures. Children may suffer unintentional hydrocarbon exposures, often ingestions, with a risk of pulmonary hydrocarbon aspiration. More concerning is a trend toward greater intentional abuse of volatile hydrocarbon inhalants by adolescents and young adults. This form of substance abuse, often termed volatile substance abuse (VSA), is a growing problem worldwide.

One can predict many of the physical properties of hydrocarbons by knowing the molecular shape and size (number of carbon atoms in the molecule’s chain). The nonpolar, covalent bonds between carbon-carbon and carbon-hydrogen atoms produce dispersion forces, which result in the attraction between hydrocarbon molecules. These same forces repel polar molecules (e.g., water) and make hydrocarbons generally hydrophobic. Once dissolved in aqueous solution, nonpolar hydrocarbons can transit rapidly through lipid membranes, including cell membranes and the blood-brain barrier. Small, light, aliphatic hydrocarbons with up to 4 carbons are gases at room temperature; those with 5 to 19 carbon molecules are liquids; and longer molecules form solids or paraffins. Branching in the molecule destabilizes intermolecular forces, so less energy is required to separate molecules. This makes it easier for a molecule to leave the liquid phase and enter the vapor phase (to volatilize). Therefore, for a given molecular size, more branching means a lower boiling point, and the compound is typically more volatile. Gaseous or volatilized hydrocarbons are likely to cause toxicity by inhalation.
Lipid-soluble solvents (aromatic, aliphatic, or halogenated hydrocarbons) are more likely than water-soluble hydrocarbons (alcohols, ketones, or esters) to cause acute central nervous system (CNS) effects. Clinicians are familiar with these effects from experience with inhaled anesthetic agents, which cause CNS sedation similar to that resulting from other hydrocarbons. The Meyer-Overton hypothesis suggests that inhaled anesthetics dissolve into some critical lipid compartment of the CNS and cause generalized inhibition of neuronal transmission. This mechanism is probably oversimplified, but it helps to explain partly the nonspecific inhibition of neuronal transmission that hydrocarbons produce in the CNS. Specific membrane interactions may also contribute to this process, and several receptor-mediated interactions are known to occur.

Specific physical properties of ingested hydrocarbons help to predict the risk of pulmonary aspiration (Table 152.1). In particular, viscosity, surface tension, and volatility determine aspiration potential and the contribution to pulmonary toxicity. Viscosity is a measure of a fluid’s resistance to flow, commonly described in units of Saybolt universal seconds (SUS). This property is not the same as the fluid’s density; in fact, these two properties correlate poorly.

Low-viscosity substances (less than 60 SUS), such as turpentine, gasoline, or naphtha, have higher tendency for aspiration in animal models. A lower viscosity value predicts a higher risk. The U.S. Consumer Products Safety Commission now requires child-resistant packaging for products that contain 10% or more hydrocarbons and have a measured viscosity less than 100 SUS.

Surface tension indirectly measures dispersion forces between molecules in a fluid, but it also characterizes the interaction with the surface that the fluid contacts. This property can be quantified on a modified Wilhelmy balance, which measures adherence of the fluid along a surface (“the inability to creep”). In theory, the lower the surface tension is, the higher is the aspiration risk. A lower surface tension value predicts a higher risk.

Volatility is the tendency for a liquid to enter the gas phase. Hydrocarbons that are highly volatile have a high vapor pressure and so tend to vaporize, enter the lungs, displace oxygen, and cause hypoxia. A higher volatility value predicts a higher risk.

**MECHANISMS OF TOXICITY**

Although organ-specific pathophysiology is often unique to individual agents, much of the toxicity of hydrocarbons results from their ability to dissolve fats or, similarly, to diffuse across hydrophobic barriers intended to protect anatomic structures (e.g., lipid bilayers, myelin). Hydrocarbon solvents cause irritation of skin and mucous membranes. Recurrent or prolonged contact results in “defatting” of skin, dissolving lipid components, and disrupting the normal architecture of the stratum corneum.

Most hydrocarbons are flammable or combustible. Under appropriate conditions, most hydrocarbons can explode. The widespread availability of hydrocarbons and their use as organic solvents account for the frequent finding of stored quantities of these solvents in clandestine illicit drug laboratories and other places. Storage and use of these flammable agents appreciably contribute to the health hazards of these facilities.

**SKIN EFFECTS**

The skin is a common site of contact and a potential portal of entry for hydrocarbons. Skin is composed of both hydrophilic and hydrophobic elements. Agents that contain both hydrophobic and hydrophilic regions (glycol ethers, dimethylformamide, dimethylsulfoxide) are highly absorbed. Dermal absorption usually constitutes a small fraction of the hydrocarbon dose absorbed by other routes (e.g., inhalation), however. The absorbed dose depends on the surface area exposed, the duration of contact, and skin’s integrity (e.g., cut, abraded).
GASTROINTESTINAL EFFECTS
Ingested hydrocarbons typically cause local gastrointestinal (GI) irritation. Most hydrocarbons are poorly absorbed from the GI tract.

Chlorinated hydrocarbons are often hepatotoxic. Carbon tetrachloride is a prototype hepatotoxin that causes centrilobular necrosis through a reactive intermediate metabolite. Other halogenated and nonhalogenated hydrocarbons have been associated with hepatic insult, including trichloroethylene, tetrachloroethylene, benzene, and even petroleum distillates. Vinyl chloride is a well-known hepatic carcinogen.

PULMONARY EFFECTS
Gaseous or volatilized hydrocarbons can be inhaled, thus displacing alveolar oxygen and causing hypoxia. Contact with lung tissue results in interstitial inflammation, polymorphonuclear infiltration and exudate, intraalveolar edema and hemorrhage, hyperemia, bronchial and bronchiolar necrosis, and vascular thrombosis. These results likely reflect both direct cytotoxicity and disruption of the surfactant layer that lead to poor oxygen exchange, atelectasis, and pneumonitis, with reductions in lung compliance and total lung capacity.

Severe hydrocarbon pneumonitis also results from intravenous injection of a hydrocarbon. In animals, intravascular hydrocarbons injure the first capillary bed encountered. The clinical course after intravenous hydrocarbon exposure mirrors that of aspiration injury.5

CARDIAC EFFECTS
Many hydrocarbons are acutely cardiotoxic. Especially important is their propensity to induce tachyarrhythmias. The mechanism by which hydrocarbons cause malignant rhythms is poorly characterized, but some of these agents can precipitate ventricular tachycardia or fibrillation and can cause sudden death.

Endogenous or exogenous catecholamines (e.g., epinephrine) are proarrhythmic. Hydrocarbons enhance this potential and are said to sensitize the myocardium to the arrhythmogenic effects of catecholamines. Essentially every class of hydrocarbon compounds, including general anesthetic agents, can sensitize the heart. Some classes carry a high risk, however, and others sensitize the myocardium modestly, if at all. The ability of these substances to sensitize the heart constitutes an accepted system for grading halocarbon (e.g., Freon) toxicity. Unsaturated, aliphatic hydrocarbons (e.g., ethylene) and aliphatic ethers have been studied but do not appear to be sensitizers. Other unsaturated compounds (e.g., acetylene), are weak sensitizers. Aromatic hydrocarbons and, especially, halogenated hydrocarbons are often potent sensitizers.6

Sensitization appears to be mediated by slowed conduction velocity, possibly by chemical and functional changes in the membrane transport proteins at gap junctions. The major ventricular gap junction protein is composed of connexin 43. This protein is regulated by phosphorylation, such that the dephosphorylated state of the hexamers in the channel is associated with greater gap junction resistance. In the presence of epinephrine, halocarbons increase gap junction resistance in myocardial tissue and slow conduction velocity.7

NERVOUS SYSTEM EFFECTS
The mechanism by which hydrocarbons depress consciousness is unknown. Diffusion across the blood-brain barrier with neuronal membrane stabilization provides the foundation of the Meyer-Overton hypothesis. To date, no specific receptor wholly explains this generalized effect. In cases of pulmonary toxicity, hypoxemia may contribute to depressed consciousness.8

Chronic solvent abuse leads to irreversible CNS toxicity, best described in the setting of toluene abuse. Volitional abusers demonstrate loss of cerebral white matter, with a characteristic syndrome of cognitive and motor deficits. Autopsied brains of long-term toluene abusers show profound atrophy and mottling of the white matter, as though the lipid-based myelin had been dissolved away. Microscopic examination shows a consistent pattern of demyelination, with relative preservation of axons. These pathologic features correlate with the clinical syndrome of subcortical dementia.9 Mild cognitive deficits show improvement after 6 months of abstinence. In patients with advanced disease, regardless of the exposure history, full recovery is unlikely.10

Exposure to n-hexane or to methyl n-butyl ketone (MnBK) can cause peripheral neuropathy. This toxic axonopathy appears to result from 2,5-hexanediol, a metabolic intermediate common to both agents. The mechanism appears to involve decreased phosphorylation of neurofilament proteins, with disruption of the axonal cytoskeleton.11

Radiologically and histopathologically, prolonged and repeated exposures to toluene are associated with brain demyelination. Although the mechanism of this process is not fully understood, it is presumed to result from dissolution of myelin by the solvent. Toluene encephalopathy is characterized by a specific constellation of findings, alternatively described as “subcortical dementia,” “white matter dementia,” or “toxic leukoencephalopathy.” Findings include the following: loss of cortical gray matter–white matter differentiation; atrophic changes in the basal ganglia, cerebellum, pons, and thalamus; and thinning of the corpus callosum. Changes noted on magnetic resonance imaging appear to progress in a lifetime dose–dependent fashion.12 Unfortunately, toluene is an addictive substance, and progression of abnormalities is likely with persistent use. Resolution of neurologic abnormalities has not been documented once white matter loss becomes radiographically evident. Complete recovery from solvent encephalopathy is not considered likely, even with abstinence or removal from exposure.10

RENAL EFFECTS
Halogenated hydrocarbons may be nephrotoxic. Examples include chloroform, carbon tetrachloride, and ethylene dichloride. Furthermore, recurrent or prolonged toluene exposure causes distal renal tubular acidosis. Sodium loss in the urine may transform the initial non-gap metabolic acidosis into anion gap–positive metabolic acidosis. Toluene’s principal metabolite, hippuric acid, contributes to the elevated anion gap. Renal potassium loss may be severe and can result in symptomatic hypokalemia. In one series, distal renal tubular acidosis was seen in 44% of hospitalized paint sniffers.13

OTHER EFFECTS
Methylene chloride and other halomethanes are metabolized to carbon monoxide by CYP 2E1 (a member of the cytochrome P-450 enzyme system). Significant and prolonged carboxyhemoglobin levels can be measured after inhalational
or dermal exposures. This metabolic toxicant appears to be exclusively generated by halomethanes.

Some hydrocarbon agents contain nitrogenous moieties, and mixtures may contain coloring additives (e.g., aniline) that can induce methemoglobinemia. Benzene is directly hematotoxic, and it is associated with hemolysis, aplastic anemia, and acute myelogenous leukemia. Because of benzene’s cancer risk, toluene has largely replaced benzene in many commercial products worldwide.

### PRESENTING SIGNS AND SYMPTOMS

The route of exposure considerably influences the organs affected. The principal organ systems affected by hydrocarbons are the skin (from dermal contact), the GI system (when ingested), the CNS, and the lungs. Some classes of hydrocarbons are cardiotoxic. Certain agents may cause organ-specific toxicity to cranial or peripheral nerves, the liver, or the kidneys. Typical presenting symptoms can be found in Table 152.2.

The intentional inhalation in VSA can be challenging to diagnose because affected patients frequently withhold relevant history. Several common inhalational techniques have been identified. Sniffing involves inhaling vapor from an open container. Huffing involves placing a volatile hydrocarbon in a rag or cloth, then covering the nose and mouth with the cloth or rag and inhaling the agent through it. Bagging implies placing the substance inside a plastic (or other) bag and then putting the bag over the face to inhale hydrocarbon vapor.

Respiratory findings are uncommon after inhalation, but the patient may manifest tachypnea or cyanosis or may suffer sudden cardiac arrest. Classically, cardiac arrest occurs after a sudden fright or physical exertion (e.g., running to avoid an authority), with a sudden catecholamine surge and a sensitized heart. This phenomenon is termed the sudden sniffing death syndrome.

Cutaneous findings may be the chief complaints, with dermal exposure to solvents from work or hobbies. Drying, cracking, pitting, or eczematous lesions occur in up to 9% of workers who are repeatedly exposed. Allergic reactions are uncommon but may be seen with exposure to certain essential oils or to pine oil. Nonspecific skin irritation is the most common finding, and it may progress to blistering or contact dermatitis with recurrent, prolonged, or protracted VSA. With continued or recurring exposure, the skin changes may even progress to partial- or even full-thickness chemical burns. When the dermatitis involves the skin surrounding the nose and mouth, it has been dubbed “huffer’s rash” (Fig. 152.1). Abusers of volatile solvents may have telltale paint, shoe-shine, or solvent stains on clothes or skin. Nonfreezing cold injury (frostbite) may occur on or about the face because of intentional release of liquid hydrocarbon propellant, which cools as it suddenly exits its container (Fig. 152.2).

Hydrocarbons cause CNS depression.Transient excitation may initially occur after inhalation or ingestion, but early sedation is more common. Initial findings include behavioral changes, impaired sense of smell, impaired concentration, and mildly unsteady movements or gait. As with alcohol or other sedatives, mild exposures produce euphoria, likely contributing to abuse potential. Further acute exposure leads to slurred speech and progressive incoordination. Physical signs are nystagmus, tremor, spasticity with hyperreflexia, abnormal plantar reflexes, hearing loss, impaired vision, and a broadband, staggering gait. Pain inhibition explains why hydrocarbons were chosen as general anesthetic agents. Stupor, lethargy, or obtundation is seen in overdose. Coma and seizures occur in up to 3% of cases.14

Chronic CNS dysfunction occurs in recurrent abusers of volatile substances, and reports include optic neuropathy, sensorineural hearing loss, equilibrium disorders, ataxia, and cognitive deficits. Occupational solvent exposures are also associated with persistent CNS abnormalities, although the exposures and the clinical findings are typically less impressive than those in habitual VSA. Most published reports involve exposure to toluene, a very common workplace and household hydrocarbon solvent. Neurologic deficits are tremor, ataxia, impaired fine-motor skills, and mild cognitive defects. Long-term occupational exposures are associated with a clinical syndrome consisting of fatigue, poor short-term memory, attention difficulties, visuospatial abnormalities, personality changes, and mood disorder. Clinically, this presentation has been dubbed “the painter’s syndrome.”

Abdominal pain and vomiting are common, and diarrhea is likely after ingestion, particularly of insoluble hydrocarbons (mineral oil, paraffins). Vomiting increases the risk of pulmonary aspiration.

A typical case in the emergency department (ED) involves a young child who is suspected to have unintentionally ingested a hydrocarbon mixture. Infrequently, a parent may have witnessed the ingestion; more typically, the situation was discovered shortly thereafter. The caregiver often identifies the specific agent. A parent may report that the child was coughing, gagging, or vomiting, or that he or she noticed an odor of the suspected hydrocarbon. If the ingestion was unobserved, it may be difficult to quantify the amount ingested, but a “worst case scenario” can often be ascertained. A history of coughing, choking, or vomiting should heighten the ED’s suspicion of pulmonary aspiration. Respiratory findings include coughing, choking, gagging, grunting, tachypnea, retractions, fever, cyanosis or poor coloration, and abnormal sounds on chest auscultation. Mental status depression is common in patients with larger ingestions but may not occur for 30 to 60 minutes after ingestion. In a prospective, multicenter study of 760 pediatric kerosene ingestions, no association was found between the age of the patient and the amount ingested. The risks of pulmonary toxicity and of CNS depression were significantly higher in children who ingested more than 30 mL of kerosene (according to history). The incidence of pulmonary aspiration was higher in children who vomited after ingestion.15

**RED FLAGS**

- History of coughing, choking, or vomiting should heighten the suspicion for pulmonary aspiration.
- Sudden sniffing death syndrome classically occurs after a sudden fright or physical exertion (e.g., running to avoid an authority), with a sudden catecholamine surge and a sensitized heart.
- Abusers of volatile solvents may have telltale paint, shoe-shine, or solvent stains on clothes or skin.
- Nonfreezing cold injury (frostbite) may occur on or about the face; it is caused by intentional release of liquid hydrocarbon propellant, which cools as it suddenly exits its container.
- Hypokalemia, with consequent muscle weakness or arrhythmia, may be the presenting complaint in abusers of volatile substances in whom renal tubular acidosis develops from recurrent toluene exposure.
- An adolescent or teen who presents to the emergency department with sudden death or a malignant tachyarrhythmia (especially ventricular tachycardia or ventricular fibrillation) must be considered to have been abusing hydrocarbons unless the emergency physician is able to demonstrate otherwise.
- Hydrocarbons do not generally affect systemic vascular resistance, so coingestants should be considered in the persistently hypotensive patient.
- Hypotension may relate to excessive positive end-expiration pressure (PEEP), and reducing PEEP may improve hemodynamics.
audible abnormalities on chest auscultation, fever, leukocytosis, and abnormalities on chest radiograph (Fig. 152.3). These findings do not differ clinically from those of community-acquired pneumonia. Only the history differentiates the two entities. The elevated temperature initially noted in hydrocarbon aspiration often spikes at 8 to 12 hours, then declines over several days, unless bacterial superinfection intervenes. For an asymptomatic patient with hydrocarbon ingestion, however, early radiography does not help predict aspiration pneumonitis, and it is not cost-effective.

Results of bioassays and serum hydrocarbon levels are rarely available to the emergency physician and have little to no value in management of hydrocarbon exposure. These measurements are available through reference laboratories for occupational monitoring or to document exposure in forensic cases.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis in hydrocarbon exposure is usually limited because the history often elucidates the exposure. Some possible differential diagnoses include adult respiratory distress syndrome, toxic alcohol exposure, barbiturate or benzodiazepine toxicity, and toluene exposure.

The diagnostic evaluation of a patient with hydrocarbon exposure depends heavily on the known patterns of toxicity associated with specific hydrocarbon agents and the route of exposure. It is more crucial to obtain and verify the history, with particular attention to identifying the specific type and composition of the agent or agents involved. The route of exposure should direct the clinician to the anticipated target organ or organs, which guide testing.

Renal function, serum electrolyte levels, and acid-base status should be evaluated in all patients with a history of chronic or recurrent toluene exposure. Liver transaminases and bilirubin should be assayed in patients with significant exposure to halocarbons or to benzene. Electrocardiographic monitoring and a formal 12-lead electrocardiogram are indicated when a patient has significant exposure to heart-sensitizing hydrocarbon agents. Head computed tomography and magnetic resonance imaging are valuable to assess the extent of brain involvement in chronic exposures. Pulse oximetry or arterial blood gas testing helps assess the severity of pulmonary injury. Carboxyhemoglobin or methemoglobin measurements are indicated for exposures involving specific agents (see “Other Effects”).

Early chest radiography may be indicated for severely symptomatic patients, to gauge the extent of pulmonary injury and guide the inpatient placement decision. Radiographic evidence of pneumonitis may develop as early as 15 minutes or as late as 24 hours after hydrocarbon aspiration. Ninety percent of patients who have radiographic abnormalities do so within 4 hours. After the initial episode of coughing, gagging, or choking, most patients with persistent respiratory signs and symptoms have pneumonitis and radiographic changes. Typical findings in hydrocarbon pneumonitis are audible abnormalities on chest auscultation, fever, leukocytosis, and abnormalities on chest radiograph (Fig. 152.3). These findings do not differ clinically from those of community-acquired pneumonia. Only the history differentiates the two entities. The elevated temperature initially noted in hydrocarbon aspiration often spikes at 8 to 12 hours, then declines over several days, unless bacterial superinfection intervenes. For an asymptomatic patient with hydrocarbon ingestion, however, early radiography does not help predict aspiration pneumonitis, and it is not cost-effective.

Results of bioassays and serum hydrocarbon levels are rarely available to the emergency physician and have little to no value in management of hydrocarbon exposure. These measurements are available through reference laboratories for occupational monitoring or to document exposure in forensic cases.

**TREATMENT**

**DECONTAMINATION**

An algorithm for the treatment of hydrocarbon exposure is shown in Figure 152.4. The first priority in managing toxicity is to protect rescuers. Personal protection is paramount at each level of health care delivery. Second, the exposure should be removed from the patient, and the patient should be removed from the exposure. Contaminated clothing and external contamination must be removed before the patient enters any patient care or trafficked area. For most hydrocarbons, soap and water are all that are required for decontamination. Most hydrocarbons are flammable and pose a fire risk to the hospital and staff. Personal protective equipment should be worn by anyone who will touch the patient or any articles brought with the patient. Once the patient is externally decontaminated, standard precautions generally suffice in the ED.
Potential hydrocarbon exposure

Contaminated clothing and external contamination must be removed prior to placement in treatment area (caregivers should wear protective gear)

Soap and water to remove any remaining hydrocarbon

History with attention to specific type and composition of agents involved

- IV, monitor, pulse oximetry
- Chem panel, ABG, LFTs, ECG
- CT or MRI for chronic exposures
- Carboxyhemoglobin or methemoglobin if indicated
- CXR if symptomatic, not an early predictor of aspiration

Pulmonary interventions:
- Intubation as needed
- Bronchodilators
- PEEP
- High-frequency jet ventilation (HFJV)
- Consider extracorporeal membrane oxygenation (ECMO)

Tachyarrhythmia

Propranolol
- Adult: 1-3 mg/dose intravenously, not faster than 1 mg/min. Repeat every 5 min until desired response, or to maximum 5 mg
- Pediatric: 0.01-0.1 mg/kg/dose over 5 minutes until desired response. Maximum 1 mg infants, 3 mg children

OR

Esmolol
- Adult: 500 mcg/kg IV over 1 min. Follow load with 50 mcg/kg/min infusion for 4 minutes. If inadequate response, repeat loading dose: 500 mcg/kg intravenous infusion over 1 minute. Follow 2nd load with 100 mcg/kg/min infusion for 1-4 minutes. Reevaluate for effect

Gastric emptying:
- HCs with inherent severe toxicity (e.g., benzene)
- Coingested with a more potent toxicant (e.g., a toxic pesticide dissolved in a less toxic HC vehicle)
- Large volume of HC ingested (>30 ml)

Severe toxicity anticipated, may outweigh risks of gastric emptying or decontamination (CHAMP):
- Camphor
- Halogenated hydrocarbons
- Aromatic
- Metal-containing hydrocarbons
- Pesticides

Asymptomatic

- Observe x 6 hours (90% symptomatic by 4 hours)
- Cardiac monitor if high risk of cardiac sensitization
- 6 hour CXR

Psychiatric evaluation if indicated

Discharge reliable patients with next day follow-up

Lidocaine
- Adult: 1-1.5 mg/kg intravenous bolus, followed by IV infusion at 1-4 mg/min. Not as effective as beta-blockade

Admit to ICU or monitored setting depending on degree of symptoms, psychiatric evaluation if indicated

Soap and water to remove any remaining hydrocarbon

Fig. 152.4  Treatment algorithm for hydrocarbon (HC) exposure. ABG, Arterial blood gases; Chem, chemistry; CT, computed tomography; CXR, chest radiograph; ECG, electrocardiogram; ICU, intensive care unit; IV, intravenous; LFTs, liver function tests; MRI, magnetic resonance imaging; PEEP, positive end-expiratory pressure.
**SECTION XV ▪ TOXICOLOGIC EMERGENCIES**

**BOX 152.1 Mnemonic for Potent Hydrocarbon Toxicants: “CHAMP”**

The clinician should consider decontamination/gastric emptying when these agents are ingested:

- Camphor
- Halogenated hydrocarbons
- Aromatic
- Metal-containing hydrocarbons
- Pesticides

Gastric emptying may be useful when the hydrocarbon is extremely toxic (e.g., carbon tetrachloride), when a large volume of hydrocarbon is ingested (more than 30 mL), or when severe toxicity is predicted (Box 152.1). If gastric lavage is performed, a small-bore (not large-bore) nasogastric tube should be used, to reduce the risk of vomiting and aspiration. Activated charcoal has little ability to reduce GI absorption of hydrocarbons and may cause gastric distention and vomiting. Any role for activated charcoal in isolated hydrocarbon ingestion is limited, at best.

Most hydrocarbons cannot be removed by dialysis, but toxic agents that are water-soluble, small, highly polar molecules can be removed by dialysis. Examples are small alcohols and polyols (e.g., methanol, ethylene glycol). Small ketones (e.g., acetone) are also dialyzable. Chloral hydrate can be successfully removed by hemodialysis. Peritoneal dialysis has been employed to reduce the toxicity of both dichloroethane and trichloroethylene. Unfortunately, many hydrocarbon molecules are too large to be dialyzed. Most are lipophilic, so they dissolve into fat stores (with greater volume of distribution), thus reducing their availability in the central compartment.

Extracorporeal membrane oxygenation can successfully temporize the course of severe pulmonary toxicity. This technique is considered invasive, is not widely available, and requires special expertise. Use of extracorporeal membrane oxygenation is generally reserved for severe cases of hydrocarbon toxicity for which other available modalities have failed to achieve adequate oxygenation.

**RESUSCITATION**

Priorities of resuscitation are similar to those in any other type of poisoning. Nuances include the requirement to limit exposure of the patient and caregivers by prioritizing decontamination. The airway and systemic oxygenation should be restored and secured first. This should be achieved by any necessary means and may require high-flow oxygenation, endotracheal intubation, ventilation, and the use of bronchodilators. Positive end-expiratory pressure (PEEP) ventilation may help oxygenate patients who are persistently hypoxemic. High-frequency jet ventilation may be required and has been used successfully in this situation.

Dysrhythmias in the setting of hydrocarbon toxicity should prompt investigations into electrolyte and acid-base status, hypoxemia, hypotension, and hypothermia. Ventricular fibrillation is especially concerning because resuscitation algorithms recommend epinephrine to treat this rhythm. If the dysrhythmia can be ascertained to emanate from myocardial sensitization by a solvent, catecholamines should be avoided. Exogenous catecholamines (e.g., epinephrine) should be avoided. In this setting, lidocaine has been used successfully, as have beta-blockers.17,18

Management of hypotension may be precarious. Hydrocarbons do not generally affect systemic vascular resistance, so coingestants should be considered in the persistently hypotensive patient. Hypotension may relate to excessive PEEP, and reducing PEEP may improve hemodynamics. Rarely, some hydrocarbons can cause myocardial depression; in a patient with this finding, an inotrope (but not isoproterenol or dobutamine) should be considered. Pressors such as dopamine, epinephrine, isoproterenol, and norepinephrine must be avoided, if possible, because of the risk of myocardial sensitization.6

**TIPS AND TRICKS**

- The emergency physician should be aware of the intentional abuse of volatile hydrocarbon inhalants by adolescents and young adults, a growing problem worldwide.
- Hydrocarbons enhance the proarrhythmic potential of endogenous or exogenous catecholamines (e.g., epinephrine) and are said to sensitize the myocardium to the arrhythmogenic effects of catecholamines, so these agents should be avoided in hydrocarbon exposure.
- Mental status depression is common in larger ingestions but may not occur for 30 to 60 minutes after ingestion.
- Typical findings in hydrocarbon pneumonitis are audible abnormalities on chest auscultation, fever, leukocytosis, and abnormalities seen on chest radiograph; these findings do not differ clinically from those of community-acquired pneumonia.
- Volitional abusers demonstrate loss of cerebral white matter, with a characteristic syndrome of cognitive and motor deficits.
- Dysrhythmias in the setting of hydrocarbon toxicity should prompt investigations into electrolyte and acid-base status, hypoxemia, hypotension, and hypothermia.
- The possibility of methemoglobinemia should be evaluated in any patient who remains cyanotic once arterial oxygenation is normalized.
- Patients with hydrocarbon exposure who have no symptoms at home or on initial evaluation generally do not require gastric emptying.

**FOLLOW-UP, NEXT STEPS OF CARE, AND PATIENT EDUCATION**

Patients who demonstrate clinical evidence of toxicity, and those who are suicidal or intend self-harm, should be hospitalized.

Patients who have been observed for 6 hours after an ingestion and who demonstrate no abnormal pulmonary findings, have adequate oxygenation, are not tachypneic, and have normal chest radiography findings have a good prognosis with a very low risk of subsequent deterioration.19 These patients can be safely discharged. Care may be individualized for
asymptomatic patients with radiographic abnormalities, as well as for patients who have initial respiratory symptoms but who quickly become asymptomatic during medical evaluation. Reliable patients may be considered for discharge with next-day follow-up.

Special care should be given to patients who ingest, or who otherwise have significant toxicity from, agents known to cause cardiac sensitization, including gasoline. The findings of mental status depression, seizures, or arrhythmias attributed to a known cardiac sensitizer (or to an unknown hydrocarbon ingestion) warrant at least 6 hours of continuous cardiac monitoring.

Inhaled Toxins

Trevonne M. Thompson

KEY POINTS

• Cyanide gas and hydrogen sulfide are rapid knockdown agents.
• The key characteristic of cyanide is profound metabolic acidosis with a wide anion gap and elevation of serum lactate.
• Clinical suspicion is paramount to the diagnosis of cyanide toxicity; treatment may be required before the diagnosis is confirmed.
• Hydroxycovalamin (Cyanokit) has fewer adverse events than the cyanide kit; it has one component instead of three.
• Rescuers must wear adequate personal protective equipment, including a self-contained breathing apparatus, to remove a victim from the source of exposure to hydrogen sulfide.
• Patients who present alert, without altered mental status and with normal respiratory effort after exposure to hydrogen sulfide, should have a good outcome.
• If administered shortly after severe hydrogen sulfide exposures, sodium nitrite may improve outcome.
• The mainstays of treatment for hydrogen sulfide toxicity are 100% oxygen and meticulous supportive care.

BOX 153.1 Cyanogen-Containing Plants

| Synthetic rubber | |

CYANIDE

EPIDEMIOLOGY

Cyanide poisoning is uncommon. It is also potentially rapidly fatal. Cyanide is used in precious metal extraction, electroplating, metal hardening, photography, and various other industries. Cyanide has also been used as an agent of chemical warfare and in judicial executions.

Cyanide exists in several forms. The gaseous form is hydrogen cyanide (HCN); the salt forms are potassium cyanide and sodium cyanide. The inorganic salts release HCN gas when they are dissolved in water. Cyanogens are compounds that are metabolized to cyanide in vivo. The two clinically important cyanogens are amygdalin and acetonitrile. Amygdalin is a naturally occurring cyanogen found in the seeds of plants in the Prunus species and in the pits of other fruits (Box 153.1). Acetonitrile is found in some artificial nail removal products. Unlike other cyanide products, cyanogens may produce delayed cyanide toxicity because of the time required for their biotransformation. Cyanide gas is also released during combustion of certain natural and synthetic materials (Box 153.2). Consequently, cyanide poisoning can occur in victims of structure fires.

PATHOPHYSIOLOGY

Cyanide is a potent cellular poison. The primary clinical effect occurs through the inhibition of oxidative phosphorylation. Cyanide binds to the ferric (Fe³⁺) moiety of cytochrome oxidase aa₃, the last enzyme of the electron transport chain.¹ The net effects of cyanide poisoning are reduced oxygen consumption and conversion of aerobic to anaerobic metabolism;

ABGs, Arterial blood gas measurements.

These effects lead to profound metabolic acidosis and an elevated serum lactate concentration.

## Presenting Signs and Symptoms

The clinical presentation of cyanide poisoning is protean and depends on the route of exposure and the cyanide compound involved. The early signs and symptoms are dyspnea, headache, weakness, nausea, vomiting, diaphoresis, hypotension, tachycardia, and altered mental status. The late signs and symptoms are bradycardia, atrioventricular heart block, ventricular dysrhythmias, asystole, seizures, and coma. Exposure to any form of cyanide can result in death.

Cyanide gas is a knockdown agent, causing those exposed to lose consciousness rapidly. Patients with exposure to 300 parts per million (ppm) of cyanide gas rapidly collapse and typically do not survive to admission to the emergency department. Exposure to 100 ppm for more than 30 minutes is considered life-threatening. An oral dose of 200 mg of potassium cyanide is considered a fatal ingestion. Features of cyanide poisoning typically develop 15 to 30 minutes after ingestion of cyanide salts. Exposure to cyanogens can result in delayed symptoms and signs because the parent compound must be metabolized before cyanide is produced.

## Differential Diagnosis and Medical Decision Making

Without a history of cyanide exposure, the diagnosis is often difficult to make (Table 153.1). All medical causes of altered mental status, hypotension, and acidosis must be considered.

### Box 153.3 Differential Diagnosis of Cyanide and Hydrogen Sulfide Poisoning

The differential diagnosis of cyanide poisoning is listed in Box 153.3. Whole-blood cyanide measurement is not readily available in the emergency department. The hallmark findings in cyanide poisoning are profound metabolic acidosis with a wide anion gap and an elevation of serum lactate.

## Treatment

Aggressive supportive care and early administration of antidote therapy are the mainstays of treatment (Fig. 153.1 and
**Fig. 153.1** Diagnosis and treatment algorithm for cyanide poisoning. ABG, Arterial blood gas measurement; ECG, electrocardiogram; ICU, intensive care unit; IV, intravenous(ly).
Patients with cyanide exposure are often critically ill at presentation and may rapidly progress to respiratory and cardiovascular collapse. Antidote therapy options include the cyanide antidote kit (CAK) and hydroxycobalamin (Cyanokit).

The CAK contains three products: amyl nitrite, sodium nitrite, and sodium thiosulfate. The nitrates induce methemoglobinemia and thus allow cyanide to dissociate from cytochrome oxidase and preferentially bind to methemoglobin. This process sequesters cyanide in the serum and allows cellular metabolism to resume. The sodium thiosulfate component enhances the innate pathway of cyanide metabolism. The amyl nitrite component of the CAK is contained in pearls that are crushed to produce a vapor that is inhaled. This component together with the sodium thiosulfate component of the CAK.

3. If smoke inhalation:
   - Use only of the sodium thiosulfate component of the cyanide antidote kit, or
   - Use of hydroxycobalamin alone, or
   - Use of sodium thiosulfate and hydroxycobalamin together (cannot use same IV site)

4. If no IV access immediately:
   - Use of amyl nitrite pearls

5. Readministration of antidotal therapy if necessary

6. Admission to the intensive care unit

**Box 153.4**. Patients with cyanide exposure are often critically ill at presentation and may rapidly progress to respiratory and cardiovascular collapse. Antidote therapy options include the cyanide antidote kit (CAK) and hydroxycobalamin (Cyanokit).

The CAK contains three products: amyl nitrite, sodium nitrite, and sodium thiosulfate. The nitrates induce methemoglobinemia and thus allow cyanide to dissociate from cytochrome oxidase and preferentially bind to methemoglobin. This process sequesters cyanide in the serum and allows cellular metabolism to resume. The sodium thiosulfate component enhances the innate pathway of cyanide metabolism. The amyl nitrite component of the CAK is contained in pearls that are crushed to produce a vapor that is inhaled. This component together. In the pediatric patient, the nitrite dose must be adjusted for the hemoglobin level. **Table 153.2** provides dosing guidelines for such a situation. Both the sodium nitrite and sodium thiosulfate components of the CAK may be readministered as clinically indicated.

Hydroxycobalamin (also hydroxocobalamin, vitamin B₁₂a) is the other antidote for cyanide poisoning and is much simpler and safer to use. Marketed as the Cyanokit, it has been approved in the United States for the treatment of cyanide poisoning. Hydroxycobalamin has a high affinity for cyanide and binds with cyanide to form cyanocobalamin (vitamin B₁₂), which is excreted in the urine. Transient hypertension and a self-limited reddish discoloration of the skin, mucous membranes, and urine are the only adverse effects of hydroxycobalamin. The adult dose is 5 g administered intravenously over 15 to 30 minutes; the pediatric dose is 70 mg/kg. The dose may be repeated as clinically indicated up to a maximum of 10 g. Hydroxycobalamin can be used alone or in conjunction with the sodium thiosulfate component of the CAK. Hydroxycobalamin can be safely administered simultaneously with sodium thiosulfate, although the two agents cannot be administered through the same intravenous access site. Hydroxycobalamin and sodium thiosulfate may be synergistic in cyanide elimination. Hydroxycobalamin does not induce methemoglobinemia.

"If giving sodium nitrite empirically to a patient with no history of anemia, do not wait for hemoglobin results; assume that the hemoglobin level is 12 g/dL, and dose accordingly."
HYDROGEN SULFIDE

EPIDEMIOLOGY

Hydrogen sulfide is a known knockdown agent. It causes a patient to become rapidly comatose, with profound metabolic acidosis. Because of its rotten egg odor, it is commonly referred to as “sewer gas” or “stink damp.” In addition to being a well-known sewer hazard, hydrogen sulfide exposure can be seen in plumbing, mining, tanning, fisheries, drilling, and miscellaneous chemical manufacturing occupations. This agent can be produced by the decomposition of animal or organic material. It can also be produced by the addition of an acid to a metal sulfide. A clue to the presence of hydrogen sulfide is the blackening or tarnishing of silver coins, which results from the conversion of silver to silver sulfide on exposure to hydrogen sulfide.

PATHOPHYSIOLOGY

Hydrogen sulfide is as potent as cyanide in binding to cytochrome aa3, inhibiting oxidative phosphorylation, and leading to metabolic acidosis and impaired oxygen utilization.

PRESENTING SIGNS AND SYMPTOMS

Hydrogen sulfide is a rapid knockdown agent. An individual exposed to a large concentration of hydrogen sulfide may quickly lose consciousness. Exposure to low concentrations may cause headache, dizziness, and nausea; at higher concentrations, exposure can lead to dyspnea, chest pain, and a decreased level of consciousness. At the highest concentrations, exposures may quickly cause collapse, coma, seizures, respiratory arrest, and asphyxiation. Table 153.3 illustrates the correlation of hydrogen sulfide air concentrations with clinical effect.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The differential diagnosis of hydrogen sulfide exposure includes the many medical and toxicologic causes of altered mental status, metabolic acidosis, and hypoxia. See Box 153.3 for an illustration of the differential diagnosis of hydrogen sulfide exposure.

The sodium nitrite component of the CAK can be administered to patients presenting early after moderate to severe exposure to hydrogen sulfide. Animal evidence sup-

TREATMENT

The most important concept in hydrogen sulfide treatment is removal of the patient from the source of exposure (Box 153.5). Patients with significant signs and symptoms or a history of significant exposure should be given 100% oxygen. Comatose patients or those in severe respiratory distress should be intubated and given 100% oxygen. Principles of decontamination should be followed as indicated. The patient’s clothes should be removed, and the skin should be decontaminated using water. Ocular examination with fluorescein and irrigation with saline solution are appropriate to address ocular exposures.

Table 153.3 Hydrogen Sulfide Air Concentrations and Clinical Effects

BOX 153.5 Treatment of Hydrogen Sulfide Poisoning

1. Remove the patient from the source of exposure by using a self-contained breathing apparatus.
2. Decontaminate the patient with water.
3. Administer 100% oxygen.
4. Intubate if the patient is comatose or has severe respiratory distress, and provide 100% oxygen.
5. If the patient is hypotensive, provide intravenous fluids and inotropes or pressors.
6. In moderate to severe cases in patients who present early, administer sodium nitrite: 300 mg (10 mL of 3% solution) over 2 to 4 minutes in adults. Measure methemoglobin levels 30 minutes after infusion.
7. Hyperbaric oxygen therapy may be tried in patients with moderate to severe cases if it is readily available at the treating institution.
Hyperbaric oxygen therapy (HBOT) has been used to treat hydrogen sulfide poisoning with anecdotal success. Its use is based on a theoretical benefit, and the indications are controversial. Transfer of an unstable patient for HBOT is not justified by the current literature. HBOT may be considered if it is readily available at the treating institution.

**FOLLOW-UP, NEXT STEPS OF CARE, AND PATIENT EDUCATION**

Patients exposed to hydrogen sulfide who are asymptomatic at the scene can be monitored for a short observation period of approximately 4 hours and safely discharged. Patients with a history of significant exposure or those with moderate to severe symptoms should be admitted to an intensive care unit for close monitoring and meticulous supportive care.

REFERENCES

Ethanol use is a common part of our society, as evidenced by the knowledge that approximately 80% of adults in the United States have consumed ethanol-containing beverages during their lifetimes. Mild to moderate consumption (up to one drink/day for women and two drinks/day for men) has been shown to have beneficial cardiovascular effects, including a decreased risk of myocardial infarction and stroke, as well as overall decreased mortality (Box 154.1).

Despite these possibly beneficial effects of alcohol, it has been found to be a top 10 cause of preventable deaths among all age groups in the United States. Additionally, approximately 9% of adults meet the diagnostic criteria for alcohol abuse and alcoholism. This maladaptive behavior can lead to numerous individual medical complications and societal problems, including motor vehicle collisions, assaults, homicide, suicide, and domestic violence. An estimated 7.6 million emergency department (ED) visits per year are for alcohol-related diseases and diagnoses.

Alcohol withdrawal is seen in the ED in various forms and stages, including early withdrawal, hallucinosis, seizures, and fully developed delirium tremens (DT). DT, a severe withdrawal syndrome defined by the presence of tremors, seizures, and delirium, develops in 5% of patients who develop symptoms of alcohol withdrawal and itself carries a 5% to 15% risk of mortality. Among patients admitted to the hospital with a diagnosis of alcohol withdrawal, the following clinical features have been found to be associated with an increased risk of death: underlying liver disease, the need for endotracheal intubation, hyperthermia, persistent tachycardia, and the use of physical restraints.

**PATHOPHYSIOLOGY**

**ALCOHOL INTOXICATION**

Ethanol is readily absorbed from the gastrointestinal (GI) tract and is primarily metabolized by the liver through the alcohol dehydrogenase pathway (Fig. 154.1). Metabolism of ethanol differs in men and women. Although alcohol dehydrogenase is found in gastric mucosa and other tissues, women seem to have less ability to metabolize it by the gastric route. Long-term ethanol users or those with high alcohol levels also use a second pathway, the microsomal ethanol-oxidizing system.

Ethanol is a central nervous system (CNS) depressant involving multiple receptors and pathways. Likely its greatest effect is in enhancing gamma-aminobutyric acid (GABA) inhibitory action. Ethanol is also known to block the excitatory N-methyl-D-aspartate (NMDA) glutamate receptor, thus leading to further CNS depression.

The level of CNS depression depends on many factors affecting absorption and elimination, including age, weight,
gender, the presence of food, gastric motility, the speed of consumption, and long-term alcohol use. Ethanol intoxication in most states is legally defined as a blood alcohol concentration (BAC) of 80 to 100 mg/dL (0.08 to 0.1% BAC). Elimination rates vary greatly, but a rate of 20 mg/dL/hour can be assumed for most intoxicated patients in the ED, regardless of initial alcohol level or chronic alcohol use.16,17 Because alcohol follows zero-order kinetics, some sources advocate drawing two ethanol levels to determine the individual patient’s exact rate of ethanol clearance, although this is most often medically unnecessary.

**ALCOHOL WITHDRAWAL**

Alcohol withdrawal is best described as a pathologic excitation of the CNS and autonomic systems. GABA receptors are desensitized and downregulated in chronic ethanol use, with a resulting decrease in activity of the inhibitory effects of GABA when a patient reduces ethanol consumption. The excitatory glutamate neurotransmitter system is blocked by GABA in the presence of ethanol, and this blockade leads to receptor upregulation in chronic alcoholism and excitation during withdrawal.17 With repeated episodes of alcohol withdrawal, the patient will have more severe withdrawal, a phenomenon known as “kindling.”18 Cessation of alcohol consumption may be inadvertent, as in the patient who is unable to tolerate oral intake because of vomiting or in the hospitalized patient whose access to ethanol is restricted.

**PRESENTING SIGNS AND SYMPTOMS**

Ethanol use is associated with many disease states affecting many organ systems in the body. The Wernicke-Korsakoff syndrome bears special mention. This syndrome complex is composed of two disease processes, Wernicke encephalopathy and the Korsakoff amnestic state, which can manifest individually or concomitantly.

Classically, Wernicke encephalopathy consists of the following: ocular abnormalities such as nystagmus and motor palsies, seen in 29% of cases; ataxia, seen in 23% of cases; and mental status change, seen in 82% of cases. Presentations with this classic triad are rare, with only 10% of confirmed cases having all three symptom types.19

The Korsakoff amnestic state refers to the syndrome of memory deficits found in long-term alcohol abusers. Anterograde and retrograde amnesia is present, and confabulation is common. Thiamine deficiency is the cause, and ataxia and memory loss may persist despite treatment.

The CNS-depressive effects of ethanol range from diminished fine-motor control to coma and respiratory depression. Because of greater tolerance, patients with chronic alcoholism may exhibit a high level of functioning despite a high BAC. The intoxicated patient often presents with the smell of ethanol on the breath, slurred speech, emotional lability, and difficulty with coordination. Death can occur from respiratory depression or aspiration.

Alcohol is related to an estimated 35% of injury-associated ED visits.20 In the setting of trauma, ethanol intoxication generally should not lower the Glasgow Coma Scale score dramatically; whenever a low score is found, further CNS evaluation is warranted.21

**ALCOHOL WITHDRAWAL**

The patient in ethanol withdrawal usually presents to the ED approximately 24 hours after a significant decrease or cessation of ethanol consumption. The patient is anxious, tremulous, tachycardic, hypertensive, and hyperreflexic and may complain of sleep and GI disturbances.

Alcohol withdrawal syndrome represents a spectrum of disease, ranging from minor to major. An accompanying time frame within this spectrum of disease shows significant
overlap between timing and the signs and symptoms. Minor withdrawal begins within 6 to 24 hours and is characterized by hyperstimulation. Major withdrawal syndrome begins after 24 hours and peaks at approximately 48 to 72 hours. It may have any or all of the following features: progression of excitatory signs and symptoms, hyperpyrexia, seizures, altered mental status, hallucinations (visual, auditory, or tactile), and delirium.

True DT is rare and constitutes the most severe form of withdrawal, although patients may mistakenly equate it with generalized withdrawal syndrome. DT occupies the far end of the spectrum, and it consists of substantial tremor, autonomic hyperactivity, profound confusion, fever, and hallucinations (Fig. 154.2).²²

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The diagnosis of ethanol intoxication is mainly one of exclusion, and a history consistent with ethanol consumption is important. The initial approach to the patient should be the same as for any patient with altered mental status. Traumatic injuries and coingestions (acetaminophen, illicit drugs, toxic alcohols) should be high on the differential diagnosis list (Box 154.2).

**Box 154.2 Differential Diagnosis of Ethanol Intoxication and Withdrawal**

**Intoxication**
- Traumatic head injury
- Cerebrovascular accident
- Metabolic derangements (hypoglycemia)
- Hypoxia
- Drug ingestion
- Central nervous system infections

**Withdrawal**
- Infections (meningitis, encephalitis, sepsis)
- Toxicidromes (sympathomimetic, anticholinergic)
- Thyrotoxicosis
- Neuroleptic malignant syndrome
- Heat stroke
- Acute psychosis
- Withdrawal from other sedative-hypnotic drugs (benzodiazepines, barbiturates) and from drugs used to treat spasticity (baclofen)

A history of previous ethanol withdrawal or of alcohol abuse with decreased intake or cessation of alcohol is the key to the diagnosis of ethanol withdrawal. Diagnostic testing for the acutely intoxicated patient should be guided by suspicion of concomitant disease states and potential traumatic injury. A BAC measurement is necessary only to confirm a diagnosis or to guide treatment.

Patients presenting in withdrawal may mandate a comprehensive evaluation, but the same guidelines apply as for the intoxicated patient. The laboratory tests vary but may include a complete blood count, serum glucose measurement, blood chemistry panel with a full set of electrolyte measurements, urinalysis, toxicology screen, electrocardiogram, chest radiography, and head computed tomography. Lumbar puncture for cerebrospinal fluid analysis may be indicated if subarachnoid hemorrhage or CNS infection is in the differential diagnosis.

**TREATMENT**

**ALCOHOL INTOXICATION**

Supportive care is the mainstay of treatment for acute ethanol intoxication (Fig. 154.3). Airway and breathing must be assessed in the comatose patient, and endotracheal intubation, although rarely needed, should be used for airway protection if necessary. Circulation should be assessed, and isotonic intravenous fluids should be given initially for patients with hypotension or volume depletion.

In the comatose patient, naloxone (0.8 mg) should be considered, and glucose (25 to 50 g intravenously) should be given to a hypoglycemic patient. Thiamine (100 mg intravenously) can be given before glucose administration to prevent or treat Wernicke encephalopathy, but glucose administration need not be delayed.²³ Electrolyte and thiamine replacement can be achieved orally if the patient is tolerating oral intake, is not at risk of aspiration, and is not being treated for active Wernicke encephalopathy. Routine multivitamin replacement with vitamin B₁₂ and folate in patients presenting with alcohol intoxication is unnecessary.²⁴

**ALCOHOL WITHDRAWAL**

Patients who present to the ED with signs and symptoms of alcohol withdrawal should be evaluated using the Revised Clinical Institute Withdrawal Assessment for Alcohol (CIWA-Ar) scale to aid in determining the severity of withdrawal (Box 154.3). Initial treatment should focus on resuscitation with fluids, replacement of electrolyte deficiencies, and evaluation and treatment of concomitant diseases.

Benzodiazepines are the mainstays of treatment for withdrawal and are usually initiated when CIWA-Ar scores are

---

**Fig. 154.2 Progression of signs and symptoms of alcohol withdrawal.** Symptoms on the left predominate during the first 24 hours without alcohol and progress over the next 48 hours. DTs, Delirium tremens.
The patient with uncomplicated ethanol intoxication may be discharged home after an evaluation for associated disease states if the following criteria are met: (1) the patient is not at risk of airway or breathing complications; and (2) a responsible, sober adult is able to monitor the patient for the next 24 hours. Otherwise, the patient should be monitored in the ED until he or she is clinically and legally sober.

Patients with major ethanol withdrawal require admission and may need an intensive care unit setting. Patients with minor withdrawal may be discharged after observation for 4 to 6 hours if mental status, vital signs, and laboratory study results remain within normal limits. A short course of benzodiazepines can be considered for the patient undergoing outpatient detoxification.

Referral to an outpatient treatment program is appropriate for all patients being discharged who are recognized as having a substance abuse disorder. Options include the use of inpatient versus outpatient treatment programs and referral to Alcoholics Anonymous (AA). Because of the high incidence of underlying social and psychiatric problems, referral to the ED’s social or psychiatric worker (if available) may also be helpful.

Patients presenting to the ED with alcohol-related issues should be screened for alcohol abuse and dependence. For patients thought to have or to be at risk for alcohol dependence, brief interventions have been shown to decrease at-risk drinking in the short term and provide an opportunity to provide information on long-term follow-up. The brief intervention is described as a four-step conversation with the patient and consists of the following: (1) broach the subject,
(2) give feedback on current drinking patterns, (3) discuss readiness to change drinking habits, and (4) provide information. More information on ED-based brief alcohol interventions can be obtained at http://www.ed.bmc.org/sbirt/.

**OPIOIDS**

### EPIDEMIOLOGY

Opioids are a class of drugs that comprise natural, semisynthetic, and synthetic substances that provide analgesic and anesthetic properties by acting at opioid receptors. **Box 154.4** gives the definition of terms associated with opioids. Opioids are most commonly used in the ED for the treatment of acute pain and for procedural sedation, although ED visits for patients with chronic opioid use for both medical and nonmedical reasons have steadily increased since 2000. After 2002, opioids have become the leading cause of death from unintentional drug overdose in the United States, and they account for more deaths than heroin and cocaine combined. Opioid overdose can occur in several situations, including intentional self-injury, unintentional prescription, recreational or pediatric ingestion, and drug packing and stuffing.

### PATHOPHYSIOLOGY

Opioids as a medical class are defined by their agonist activity at opioid receptors, of which µ, κ and δ are the best described. Opioid receptor activity in the CNS, spinal cord, and GI system has widespread effects, including analgesia, anesthesia, euphoria, decreased GI motility, respiratory depression,
TIPS AND TRICKS

- Serum ethanol measurements are not needed in every patient. Obtain an ethanol measurement when needed for confirmation or to guide treatment.
- Remember to rule out any other disease process in the patient with complicated ethanol intoxication.
- Discharge time can be guided by the following: (1) calculate sober time according to ethanol level; (2) an evaluation for clinical sobriety; or (3) whether the patient is awake and directable and will be in the care of a responsible, sober adult.
- Calculate sober time as follows: (1) subtract 80 to 100 (legal limit) from the blood ethanol level; (2) divide the remainder by 20 (mg/dL/hr); the resulting number is the time to sobriety in hours.
- Opioids may have a long half-life, so additional naloxone doses may be necessary if the patient seems to return to a depressed state after initially responding to naloxone.
- In patients with cancer or long-term pain medication use who present with symptoms of opioid withdrawal, treatment of nausea and vomiting and a dose of the prescribed opioid medications are appropriate.

PRESENTING SIGNS AND SYMPTOMS

Respiratory depression leading to apnea is the primary life-threatening presentation of opioid overdose. Because respiratory depression is reliably accompanied by altered mental status or coma, a history of opioid use is often not readily available and should be considered in patients who are found unconscious and who have a decreased respiratory rate or miosis. Patients with milder opioid intoxication may present with nausea, vomiting, constipation, miosis, depressed CNS level, and depressed respiratory status. Table 154.1 contains a more extensive list of these symptoms.

The patient presenting with acute opioid overdose must be evaluated for additional emergency diagnoses, including trauma, infection (particularly in patients who inject opioids), coagulation, electrolyte abnormalities, and complications of prolonged immobility such as rhabdomyolysis, compartment syndrome, and mononeuropathies.

Certain opioids have unique toxicities that must be considered during ED evaluation (Table 154.2). Methadone, an agent used primarily for addiction therapy, is very long acting, with a half-life of more than 24 hours, and can cause prolongation of the QTc interval and torsades de pointes. Propoxyphene was taken off the market because of its tricyclic antidepressant-like sodium channel activity and association with wide complex tachyarrhythmias and negative inotropy, even at therapeutic doses. Fentanyl, particularly when given as a rapid injection, can cause chest wall rigidity that can be difficult to manage, even with naloxone and endotracheal intubation.30

Noncardiogenic pulmonary edema is an uncommon complication of opioid overdose characterized by hypoxia despite resolution of altered mental status and bradypnea, production of frothy pink sputum, and chest radiograph evidence of diffuse pulmonary infiltrates.31 Opioid-related pulmonary edema is short-lived and infrequently requires intubation, but it mandates admission to the hospital until resolution of symptoms and hypoxia. In the alert patient, noninvasive ventilation can be considered for improved oxygenation.

Patients with opioid withdrawal syndrome present with similarly varied symptoms, but as a rule they appear uncomfortable. Their symptoms may include yawning, rhinorrhea, mydriasis, piloerection, nausea, vomiting, diarrhea, myalgias, and abdominal pain. An acute withdrawal syndrome is seen after the administration of naloxone, particularly in patients with long-term opioid use with dependence.

Vital signs may include tachycardia, normal blood pressure to hypertension, and tachypnea. Another common picture of...
Differential Diagnosis and Medical Decision Making

The differential diagnosis of mild opioid intoxication should include diagnoses that cause altered mental status and hypoventilation: hypoglycemia, head injury, and overdose of other medications (alcohols, benzodiazepines, barbiturates, tricyclic antidepressants). The differential diagnosis for the patient who is ill secondary to opioid overdose is similar to that for the patient in coma; infection, cerebrovascular accident, head trauma, and other overdoses should be considered (Box 154.5).

Diagnostic testing in opioid overdose usually does not guide treatment, given that the antidote is administered before test results are available. Tests are used to evaluate for complications of opioid toxicity including arrhythmias, acute lung injury, pulmonary edema, and comorbid diseases. Electrocardiograms and chest radiographs can be useful as adjuncts in these cases. Because intravenous drug abusers are prone to numerous and severe infections, the presence of fever or persistent altered mental status in this population should prompt a rapid and broad work-up.

Urine drug testing does not guide treatment in the acute setting of opioid overdose. Opioids can be detected for up to 36 hours in the urine, although false-positive results have been...
found after ingestion of poppy seeds. The urine drug screen is also poorly sensitive for detecting use of synthetic opioids, including methadone, fentanyl, hydromorphone, hydrocodone, and oxycodone. Acetaminophen, salicylate, and ethanol measurements should be included in the evaluation for unknown ingestions. A serum chemistry panel and complete blood count can be helpful in the broader evaluation of the sick opioid-toxic patient. The serum creatinine kinase level may be elevated in patients with prolonged immobility and rhabdomyolysis. Many patients awaken after treatment with naloxone, admit to opioid overdose, and may not require any further testing.

The diagnosis of opioid withdrawal can usually be obtained based on history and examination findings. However, because patients with opioid withdrawal can appear systemically ill, other emergency diagnoses such as infection, serotonin syndrome, and sympathomimetic or cholinergic toxicity should be considered.

Diagnostic testing in patients undergoing opioid withdrawal is guided by ruling out other causes of the presenting signs and symptoms. A comprehensive chemistry panel is useful when the patient has massive vomiting and diarrhea.

**TREATMENT**

Treatment of opioid intoxication and overdose should begin with assessment of the airway, breathing, and circulatory status of the patient. Airway adjuncts such as an oral or nasal airway can be used to improve the viable airway. In patients with a decreased respiratory rate or apnea, bag-valve-mask ventilation may be necessary before intubation or naloxone administration.

Rapid administration of naloxone may preclude the need for intubation. If signs and symptoms are consistent with opioid intoxication, the antidote should be given immediately while preparations are being made for intubation. Naloxone should be administered intravenously in apneic patients, with starting doses of 0.4 to 1 mg and 2 mg in those with cardio-pulmonary arrest. Naloxone can be repeated to reach the desired effect of increased respiratory rate. A higher dose of naloxone may be required for certain naloxone-resistant opioids (e.g., fentanyl, methadone, propoxyphene). Naloxone should take effect in minutes and has a duration of action between 20 and 90 minutes. Repeat dosing or continuous infusion may be necessary for patients who have ingested long-acting opioids such as methadone and extended-release formulations.

Hypotension should be treated with intravenous fluids according to resuscitation protocols. Blood glucose levels should be checked at the bedside, and patients with hypoglycemia should receive dextrose. Care should be taken to reevaluate the patient frequently and observe him or her for a return of respiratory depression.

Activated charcoal administration may be considered only in awake or intubated patients if they had a known recent oral ingestion and especially with coingestions. Opioid-induced seizures may respond to oxygen and naloxone administration. Seizures that do not respond to naloxone may be treated with benzodiazepines. Refractory seizures should prompt investigation of a complicating or additional process such as body packing, head trauma, or other ingestions. Hemodialysis is not indicated in opioid overdose because of the large and variable volume of distribution of these agents in the body.

Treatment of opioid withdrawal in the ED is aimed at stabilization of cardiopulmonary status and symptomatic therapy. Opioid replacement should be guided by the cause of the withdrawal: cessation of prescription medications, methadone

---

**DOCUMENTATION**

**History**
- How much alcohol or opioid was ingested, by what route, and over what period?
- Other drugs ingested?
- History of delirium tremens or alcohol-related seizures?
- Was any trauma or loss of consciousness involved?
- Recent infections?
- Patterns of opioid use?
- Previous history of self-injury?

**Physical Examination**
- Stable or unstable vital signs (including repeat evaluation)?
- Does the patient look ill? Are signs of trauma present?
- Is the patient awake? Arousable? What is the Glasgow Coma Scale score?
- Cardiovascular status
- Respiratory and airway status
- Skin and musculoskeletal findings
- Eye examination: pinpoint pupils
- Findings of any repeat examinations made while the patient is in the emergency department
- Signs of intoxication at admission and discharge, especially if ethanol level was not measured

**Laboratory Studies**
- Levels of aspirin and acetaminophen; urine drug screen results if needed
- Ethanol level if measured
- Electrocardiogram and chest radiograph in patients with abnormal physical findings
- Tests for electrolyte levels, anion gap, complete blood count, serum creatinine, creatine kinase

**Medical Decision Making**
- Complex versus noncomplex alcohol intoxication
- Ruling out of concomitant diseases

**Treatment**
- Treatment strategy, including time monitored, fluid therapy, and any injuries addressed
- Decision to admit or discharge patient
- Time to administration of antidote, initial dose, redosing, or start of naloxone drip

**Patient Instructions**
- Discussion with patient regarding diagnosis, warning signs, what to do, follow-up, when to return
- Referral to outpatient primary medical follow-up and substance abuse centers
- For pediatric accidental ingestions: poison prevention counseling and child protective service notification if indicated
therapy for addiction, and decreased recreational intake. Administering missed doses of opioids and methadone replacement (20 mg orally or 10 mg intramuscularly) can be used to reverse withdrawal without overdose. Clonidine (0.1 to 0.3 mg orally every hour or in a sustained-release patch) can also help with high blood pressure and decrease withdrawal symptoms. Benzodiazepines can be used to aid in sedation and to temper withdrawal symptoms. Antiemetics can be given to the patient with persistent nausea and vomiting.

**RED FLAGS**

- Incorrectly assuming the patient is intoxicated
- Not suspecting ethanol abuse in an older patient
- Not recognizing concomitant head injury, intoxication, or associated diseases
- Not aggressively treating signs and symptoms of withdrawal
- Inappropriately discharging an acutely intoxicated patient
- Not managing the airway in a timely manner
- Not evaluating for other causes, including head trauma, infection, and cerebrovascular accident, after repeated doses of naloxone or continued altered consciousness in the patient with suspected intoxication or opioid overdose
- Not considering opioid withdrawal in patients with cancer and in other patients with long-term opioid use and treating appropriately

**FOLLOW-UP, NEXT STEPS OF CARE, AND PATIENT EDUCATION**

Patients with opioid intoxication can probably be discharged from the ED after observation and evaluation of any active comorbid diseases at presentation. Patients with uncomplicated opioid overdose can be monitored in the ED for 2 to 4 hours after reversal because the half-life of most opioids is in this range. However, patients who present with overdose from opioids with long half-lives, such as methadone, should be admitted to the hospital for continued airway monitoring. Depending on the type of opioid, the route of administration, and the amount taken, additional doses of naloxone may be required to keep the patient from experiencing opioid reintoxication.

Any patient who requires a second dose of naloxone should be observed for an extended time, and intensive care unit admission should be considered. Patients with complicated opioid overdoses requiring respiratory assistance and those with severe toxicity must be admitted to the hospital’s critical care unit.

Unlike alcohol withdrawal, opioid withdrawal is not life-threatening. Most patients may be discharged for outpatient treatment.

REFERENCES

Barbiturates were formerly the primary sedative-hypnotic agents used clinically. Currently, they are most often encountered as anticonvulsants, induction agents for anesthesia, and agents used for procedural sedation. Because the barbiturates have largely been replaced clinically by benzodiazepines due to safety concerns, their prevalence in overdoses has drastically decreased when compared with previous decades. The reported use of barbiturates among high school seniors experienced a slow but steady surge throughout the 1990s and reached a peak in 2005, only to experience a decline since then. Barbiturates accounted for only two single-substance deaths reported to poison centers in 2009.

Gamma-hydroxybutyrate (GHB) was synthesized in 1960 as an anesthetic agent. Although it found limited use in this arena, GHB gained widespread acceptance in the body-building community in the 1990s as a purported anabolic agent. More recently, it has been used as a recreational drug for its euphoric and intoxicating effects. It has also been implicated in date rape because of its “knockout” and amnesic properties.

Several nonbenzodiazepine sedatives have been introduced for sleep induction. Examples include zolpidem (Ambien), zaleplon (Sonata), and eszopiclone (Lunesta). Cases of abuse and dependence have been reported, albeit with much less frequency compared with benzodiazepines. Nonbenzodiazepine sedatives have been implicated in cases of impaired driving.

Chloral hydrate has been used as a sedative since the nineteenth century. In the early 1900s, chloral hydrate was used maliciously, added to alcoholic drinks consumed by unwary individuals to facilitate robberies. The drug-laced drink was referred to as a “Mickey Finn,” named after the owner of a Chicago bar who used these drinks to rob unsuspecting patrons. Currently, chloral hydrate is used primarily for procedural sedation.

Propofol is a short-acting sedative-hypnotic that has become widely used clinically for induction of anesthesia and procedural sedation. Despite its abuse potential, the literature is limited to case reports of toxicity from recreational use because of its limited availability to the general public. Most reported cases involve self-administration by medical personnel. Propofol is covered in greater detail elsewhere in this text.
ter. A specific benzodiazepine receptor exists on the GABA A receptor. When a benzodiazepine binds to this receptor, it promotes GABA binding to the GABAA chloride channel complex. They can also bind directly to GABA_A chloride ion channels in the CNS, and the influx of chloride into neuronal cells leads to greater CNS inhibition. As such, benzodiazepines have anxiolytic, muscle relaxant, sedative, hypnotic, amnestic, and anticonvulsant properties.

BOX 155.1 Benzodiazepines

| Short Duration (A Few Hours) | Midazolam (Versed) | Triazolam (Halcion) |
| Intermediate Duration (Up to a Day) | Alprazolam (Xanax) | Flunitrazepam (Rohypnol) | Estazolam (ProSom) | Lorazepam (Ativan) | Oxazepam (Serax) | Temazepam (Restoril) |

PATHOPHYSIOLOGY

No strict criteria exist for defining this class of drugs other than possession of sedative-hypnotic properties. Consequently, this class has large numbers of substances with varying pharmacologic mechanisms. Given such a broad definition, many other substances, such as opioids, some antipsychotics, antihistamines, and alcohol, would also be considered part of this class, except that these substances have other unique properties that set them apart.

BENZODIAZEPINES

Benzodiazepines vary in onset and duration of action according to their lipid solubility and the presence or absence of active metabolites (Box 155.1). The more lipid soluble the agent is, the more rapidly it crosses the blood-brain barrier, thus yielding a faster onset of action. The duration of action depends largely on the elimination half-life of specific agents, which can range from hours to days. The duration of action is also affected by the metabolism of certain benzodiazepines because their active metabolites extend the duration of symptoms.

The benzodiazepines produce central nervous system (CNS) depression through effects mediated by gamma-aminobutyric acid (GABA), a major inhibitory neurotransmitter. A specific benzodiazepine receptor exists on the GABA_A receptor. When a benzodiazepine binds to this receptor, it subsequently promotes GABA binding to the GABA_A receptor. Activation of the GABA_A receptor results in influx of chloride into the neuronal cell and causes CNS inhibition. As such, benzodiazepines have anxiolytic, muscle relaxant, sedative, hypnotic, amnestic, and anticonvulsant properties.

Pure benzodiazepine overdoses cause mild to moderate CNS depression. Deep coma requiring assisted ventilation can occur, especially when a benzodiazepine is used with other sedating drugs. In severe overdoses, these agents can induce cardiovascular and pulmonary toxicity, but fatalities resulting from pure benzodiazepine overdoses are rare.

BARBITURATES

The barbiturates are often classified according to their therapeutic duration of action: ultrashort-acting, short-acting, intermediate-acting, and long-acting agents (Box 155.2). In overdoses, however, the duration of action varies with dose, rate of absorption, and rate of distribution and elimination. The ultrashort-acting and short-acting agents are highly lipid soluble and rapidly penetrate the CNS, so the onset of symptoms is also rapid. In addition, the ultrashort-acting barbiturates are more highly protein bound, have higher acid-dissociation constant (pK_a) values, and have larger volumes of distribution. Long-acting agents such as phenobarbital are metabolized more slowly in the liver, with a greater fraction of unchanged drug excreted in the kidney. These factors help explain why enhanced renal elimination through alkalinization may be more effective with phenobarbital, which also has a lower pK_a than the other barbiturates, thus making it more sensitive to alkalinization. In addition, phenobarbital undergoes enterohepatic recirculation, which makes repeated use of activated charcoal potentially advantageous.

Barbiturates are primarily CNS depressants that mediate their effect through several mechanisms. The barbiturates promote GABA binding to the GABA_A chloride channel complex. They can also bind directly to GABA_A chloride ion channels in the CNS, and the influx of chloride into neuronal cells leads to greater CNS inhibition. Barbiturates may also reduce specific excitatory neurotransmission.

The reticular activating system and the cerebellum appear to be the most susceptible to the depressant effects of barbiturates. Toxicity can lead to suppression of skeletal, smooth, and cardiac muscles, with resulting depressed myocardial contractility, bradycardia, vasodilation, and hypotension (Table 155.1).

GAMMA-HYDROXYBUTYRATE

GHB is a metabolite of GABA that occurs naturally in the human brain. It is highly lipophilic and rapidly absorbed, and, unlike GABA, it readily crosses the blood-brain barrier. Presentation in a coma state and subsequent rapid recovery is characteristic of GHB overdose.
NONBENZODIAZEPINE SEDATIVES

This class can be divided into three general structural classes: imidazopyridines, pyrazolopyrimidines, and cyclopyrrolones. Their mechanisms of action are similar. They all act selectively at the benzodiazepine receptor to enhance GABA A receptor activity. Accordingly, their toxicity mimics that of the benzodiazepines.

CHLORAL HYDRATE

Chloral hydrate is absorbed completely from the gastrointestinal tract and metabolized rapidly. One of its metabolites, trichloroethanol, is also pharmacologically active and produces sedation. In the presence of ethanol, the metabolism of trichloroethanol is inhibited, with resulting increase in sedation and prolongation of the sedative effects.

Although chloral hydrate has been used for more than a century to induce sedation, its mechanism of action is still largely unknown. It probably works through effects at the GABA receptor, similar to the other sedative-hypnotic agents discussed. Chloral hydrate can also induce cardiac dysrhythmias, most likely by increasing the sensitivity of the myocardium to catecholamines.

OTHER AGENTS

Buspirone is a nonbenzodiazepine used to treat generalized anxiety. Its mechanism of action involves serotonin, rather than GABA. Although buspirone is one of the more commonly reported miscellaneous sedative-hypnotic exposures, significant toxicity from overdose is extremely rare. In one case report, overdose resulted in generalized seizure activity and subsequent full recovery.

Glutethimide, ethchlorvynol, meprobamate, and methaqualone are older sedative-hypnotic agents that have fallen out of common use. Only meprobamate is still available in the United States. All these agents appear to act by enhancing the effects of GABA.

The hallmark of sedative-hypnotic overdose is CNS depression. The degree of CNS depression depends on the dose, the specific agent, and the other agents ingested.

RED FLAGS

These signs, symptoms, and test results should prompt the clinician to search for other causes of central nervous system depression:

- Focal neurologic deficit
- Fever
- External evidence of trauma
- Seizure activity
- QRS prolongation on electrocardiogram (seen with agents that can block myocardial sodium channels, such as tricyclic antidepressants)
- Electrolyte abnormalities
- Metabolic acidosis
- Hypoglycemia
- Dysrhythmias (except with chloral hydrate)

Mild to moderate sedative-hypnotic overdoses may manifest with a reduced level of consciousness, slurred speech, and ataxia. At high doses, sedative-hypnotic agents can cause hypothermia, hypotension, bradycardia, flaccidity, hyporeflexia, coma, and apnea. These severe symptoms are more commonly encountered in barbiturate overdoses. Patients with severe overdoses may appear to be dead, with no electroencephalographic activity.

CNS, Central nervous system; MDAC, multiple-dose activated charcoal.
The differential diagnosis of sedative-hypnotic toxicity includes any condition or ingestion resulting in CNS depression. Many other substances are capable of producing profound CNS depression, including alcohol and opiates. However, care should be made not to miss other, nontoxicologic causes of CNS depression. Although sedative-hypnotic toxicity resolves with just supportive care, other mimickers of sedative-hypnotic overdose may need other acute interventions. Other diagnoses that should be considered include head trauma with intracranial hemorrhage, embolic and hemorrhagic stroke, electrolyte abnormalities, hypoglycemia, hyperglycemic crisis, hypoxemia, hypothyroidism, liver or renal failure, CNS infection, seizures, and significant alterations in temperature (Table 155.2).

Diagnostic testing should be used to help exclude other causes of altered mental status. A fingerstick blood glucose determination, pulse oximetry, and cardiac monitoring may help the clinician avoid missing hypoglycemia, hypoxemia, or dysrhythmia.

Further testing to help clarify the patient’s presentation may include serum electrolytes, blood urea nitrogen, serum creatinine, serum ethanol, blood gas analysis, chest radiograph, computed tomography of the brain, cerebrospinal fluid analysis, serum transaminases, serum bilirubin, ammonia level, blood cultures, and urinalysis. If the patient is female, a urine pregnancy test is warranted. Directed quantitative serum levels of certain drugs may also be helpful; these may include acetaminophen, salicylate, lithium, and anticonvulsants.

Most institutions have a qualitative urine drug screen available, although this screen varies by institution. Most of the screens are immunoassays that detect the presence of certain drugs or metabolites in the urine. In the case of sedative-hypnotic agents, the commonly available screens usually test for benzodiazepines. The other sedative-hypnotic agents are typically not included in most urine drug screens. The typical benzodiazepine screen identifies metabolites of 1,4-benzodiazepines such as oxazepam or desmethyldiazepam. Benzodiazepines that are not metabolized or are metabolized to other compounds remain undetected. In addition, the detection cutoff may be set at a point at which the assay may not detect certain agents that can induce effects in very small amounts. A false-negative screen result may occur with

MDAC, Multiple-dose activated charcoal.

Pear-like odor is associated with chloral hydrate. Chloral hydrate overdoses may manifest with cardiac toxicity as well as with central nervous system depression. Bullous lesions are sometimes associated with barbiturate overdoses. Rhabdomyolysis is a complication. A patient who appears brain dead after a severe sedative-hypnotic (barbiturate) overdose may not be brain dead. Use beta-blockers to treat chloral hydrate–induced cardiac dysrhythmias. Epinephrine and norepinephrine are relatively contraindicated in chloral hydrate overdose because the myocardium may have an increased sensitivity to these types of agents. The most common drug used to facilitate sexual assault is ethanol, not sedative-hypnotics. MDAC appears to be superior to urinary alkalization in enhancing the elimination of phenobarbital, and performing both procedures concurrently has no apparent benefit.
certain benzodiazepines, including alprazolam, clonazepam, and flunitrazepam. The clinician must recognize the limitations of this screen.

Quantitative benzodiazepine concentrations correlate poorly with pharmacologic or toxicologic effects and are poor predictors of clinical outcome.

A quantitative serum phenobarbital level can be helpful to document toxicity, but it is not mandatory for definitive typically management. Therapeutic concentrations of phenobarbital range between 15 and 40 mg/L. Patients with levels higher than 50 mg/L exhibit mild toxicity, whereas patients with levels higher than 100 mg/L are typically unresponsive to pain and may suffer from respiratory and cardiac depression.

**TREATMENT**

The mainstay of treatment for the patient with sedative-hypnotic overdose is supportive care, with particular attention to airway patency and respiratory status. When hypotension occurs, it should be managed with fluid resuscitation and vasopressors as needed.

Beta-blockers have been successfully used to treat cardiac dysrhythmias resulting from chloral hydrate toxicity because myocardial catecholamine sensitivity is believed to induce the dysrhythmia. Epinephrine and norepinephrine are relatively contraindicated because the myocardium may have increased sensitivity to these types of agents.

Patients who are stable after significant ingestions should receive activated charcoal as a means of preventing absorption of drugs still contained within the gastrointestinal tract. The efficacy of this procedure decays with time, so activated charcoal is typically unresponsive to pain and may suffer from respiratory and cardiac depression.

MDAC appears to be superior to urinary alkalinization for enhancing the elimination of phenobarbital. MDAC is contraindicated in patients who do not have protective airway reflexes or an otherwise secure airway. MDAC is also contraindicated in patients who have evidence of ileus or who are hemodynamically unstable.

Alkalinizing the urine with the intravenous administration of sodium bicarbonate can increase the elimination of phenobarbital. Urinary alkalinization with sodium bicarbonate to a pH of 7.5 to 8.0 can hasten the renal excretion of phenobarbital. Urinary alkalinization can be accomplished with an initial sodium bicarbonate bolus of 1 mEq/kg, followed by a continuous infusion. This infusion is made by adding 100 to 150 mEq of sodium bicarbonate to 850 mL of dextrose 5% in water and titrating it to maintain a urine pH of greater than 7.5 with an arterial pH less than 7.5. The rate must be assessed hourly to avoid excessive administration of fluid or bicarbonate, which can cause pulmonary or cerebral edema or electrolyte imbalance. Although expediting the elimination of phenobarbital from the body has theoretical benefit, no difference in clinical outcome has been shown. Alkalinization does not increase excretion of short- and medium-acting agents, which are more lipid soluble.

In patients who are not responsive to standard therapeutic measures, or in patients with renal failure, hemodialysis may help eliminate long-acting barbiturates. These agents are less protein bound and less lipid soluble that the shorter-acting barbiturates, characteristics that enhance the role of hemodialysis. Fortunately, extracorporeal elimination is rarely indicated because most barbiturate overdoses resolve with supportive care alone.

Hemodialysis can enhance the elimination of chloral hydrate and its metabolites. However, supportive measures are generally effective. Hemodialysis may have a role if a patient with chloral hydrate toxicity is not responding to conservative therapy.

Flumazenil is a specific antagonist for benzodiazepines (Box 155.3). It competitively binds at the benzodiazepine receptor, displaces benzodiazepines from the site, and inhibits GABA potentiation. Flumazenil is lipid soluble and readily crosses the blood-brain barrier to exert its effects quickly. Typically, benzodiazepine-induced sedation is reversed within a couple of minutes.

In the setting of procedural sedation, flumazenil is an excellent rescue agent for inadvertent supratherapeutic administrations of a benzodiazepine agent. Flumazenil may also be helpful in the setting of an isolated known benzodiazepine overdose. Unfortunately, this situation rarely occurs clinically. The use of flumazenil in the setting of a multiple drug overdose that includes a benzodiazepine is less clear.

Overall, for an unknown overdose, the administration of flumazenil is not indicated. Flumazenil does not antagonize
the CNS effects of alcohol, barbiturates, tricyclic antidepressants, or narcotics. Reports have noted precipitation of seizure activity in the setting of mixed overdose or benzodiazepine dependence. Because supportive therapy is usually effective in benzodiazepine overdose, the benefit of flumazenil may not outweigh the risks of administration when circumstances surrounding the toxic ingestion are unclear. Flumazenil use has been described in the setting of overdose of the newer, non-benzodiazepine sedatives. However, supportive care is usually effective in these cases as well.

**PARADOXICAL REACTIONS**

Occasionally, patients who have been exposed to sedative-hypnotic agents experience a reaction that can be characterized by an increase in psychomotor activity. This has been most commonly described in benzodiazepines. The reactions can range from increased talkativeness and excessive movement to rage and hostility. As a whole, these reactions have been termed paradoxical because they seem counter to the sedative properties of these agents.

The mechanism of these paradoxical reactions is unclear, but some characteristics seem to increase the risk of these reactions. These characteristics include the younger and older age groups, as well as underlying psychiatric disorders. A genetic predisposition to these reactions may also exist.

The use of flumazenil, haloperidol, and other agents has been described for the treatment of these reactions, with variable success. However, the mainstay of treatment should focus on supportive care. This attention to supportive care should be all that is required.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients who are symptom free from an isolated sedative-hypnotic overdose may be discharged home after a traditional 4- to 6-hour observation period. However, the events leading to the exposure may preclude discharge home. Psychiatry consultation is necessary for those patients with intentional overdoses.

Patients with prolonged sedation or other evidence of toxicity should be admitted for further observation and treatment.

Admission to a critical care setting is dictated by the severity of toxicity. Hemodynamic instability, respiratory failure, coma, severe hypothermia, and the need for hemodialysis are some indications for admission to an intensive care unit.

Hypoglycemic Agent Overdose

Mark Su

PATHOPHYSIOLOGY

The primary metabolic substrate for the central nervous system (CNS) is glucose. Usual sources of glucose are diet, endogenous production (through gluconeogenesis), and storage (through glycogenolysis). Serum glucose concentrations are relatively tightly controlled by physiologic mechanisms. After dietary sources of glucose are completely used, glycogenolysis is the major physiologic mechanism for maintaining euglycemia. Typically, an adult has enough glycogen to last approximately 6 to 8 hours. When glycogen stores are depleted, gluconeogenesis, which is fueled by amino acids from muscle, takes over. The CNS cannot make or store glucose, and it relies on the previously mentioned mechanisms to maintain normal metabolic activity during fasting periods. As glucose use exceeds glucose production and serum glucose concentrations decrease, various counterregulatory pathways are activated. Counterregulatory pathways triggered at the glycemic threshold are increases in glucagon, epinephrine, growth hormone, and cortisol. Glycemic thresholds are fairly reproducible in research studies on healthy subjects, but these thresholds can vary significantly among patients with both type 1 and type 2 DM. These thresholds also depend on other factors, such as tightness of glucose regulation, the presence of chronic hyperglycemia, and recent episodes of hypoglycemia.

Hypoglycemic agents induce hypoglycemia by various mechanisms. Insulins cause rapid transport of amino acids and glucose intracellularly. Sulfonylureas stimulate insulin secretion by binding to specific membrane receptors on the pancreatic beta-islet cell. These drugs also benefit glucose homeostasis by decreasing hepatic glucose production and improving insulin sensitivity at the receptor and postreceptor levels. Other drugs may induce hypoglycemia by inhibition of gluconeogenesis, glycogenolysis, counterregulatory hormones, or other unknown mechanisms. Ethanol, a toxin commonly encountered in the ED, inhibits gluconeogenesis by depleting nicotinamide adenine dinucleotide and also inhibits the effects of cortisol, growth hormone, and epinephrine.

PRESENTING SIGNS AND SYMPTOMS

The symptoms of hypoglycemia can be divided into two basic groups: hyperadrenergic symptoms and neuroglycopenic...
Early Conditions - mediated through altered brain activity; the resulting constellation of signs and symptoms of hypoglycemia is termed neuroglycopenia. Three neuroglycopenic syndromes are described: acute, subacute, and chronic. Both subacute and acute forms of neuroglycopenia may manifest as acute neurologic deficits (e.g., transient hemiplegia), loss of consciousness. Precipitous loss of consciousness may occur as the sole manifestation of subacute neuroglycopenia.

Neuroglycopenic Symptoms
- Decreased cognitive ability
- Agitation and emotional lability
- Sensations of warmth (despite cool, clammy skin)
- Blurred vision
- Slurred speech
- Lethargy
- Confusion
- Unresponsiveness
- Focal neurologic deficits
- Psychotic behavior
- Seizures

Symptoms (Box 156.1). Hyperadrenergic symptoms are more common with a rapid decrease in glucose and result from autonomic nervous system stimulation (both sympathetic and cholinergic). The other clinical features of hypoglycemia are autonomic nervous system stimulation (both sympathetic and parasympathetic).

Hypoglycemia may be a complication of the illness, drug interactions, or other iatrogenic factors. Hypoglycemic agents can be divided according to their route of administration (i.e., parenteral or oral). Insulins and the newer agents, incretins (e.g., exenatide [Byetta], liraglutide [Victoza]), are the only medications for the treatment of DM that are given parenterally. Many antidiabetic medications are given orally, including the sulfonylureas (e.g., glibenclamide [Diabeta], glipizide [Glucotrol]), meglitinides (e.g., nateglinide [Starlix], repaglinide [Prandin]), biguanides (e.g., metformin), thiazolidinediones (e.g., rosiglitazone [Avandia], pioglitazone [Actos]), and α-glucosidase inhibitors (e.g., acarbose [Precose]). Of all these antidiabetic drugs, only a few classes are commonly associated with hypoglycemia—the insulins, sulfonylureas, and meglitinides.

For adults with DM, insulin treatment is the most common cause of hypoglycemia. Factors associated with higher frequency of hypoglycemia in patients with type 1 DM include lower hemoglobin A1c, higher daily insulin requirements, longer duration of DM, and a previous history of hypoglycemia. Approximately 25% of patients with DM are unable to recognize impending hypoglycemia because of a lack of autonomic warning symptoms; this characteristic is also an important predictor of hypoglycemia. Patients with insulin-dependent type 2 DM are also susceptible to hypoglycemia, especially if their disease has been treated with insulin for a long time and if their DM is tightly controlled.

For patients who are taking oral agents rather than insulin, sulfonylureas are a common cause of hypoglycemia. According to the 2010 annual report of the American Association of

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Hypoglycemia has numerous causes and may be classified into the following three categories: (1) postprandial, (2) fasting, and (3) drug- or toxin-induced (Table 156.1). In healthy patients, fasting hypoglycemia is usually the result of unintentional or intentional drug ingestion and insulinoma. In patients who are severely ill or hospitalized, hypoglycemia may be a complication of the illness, drug interactions, or other iatrogenic factors.

The 2010 annual report of the American Association of...
Poison Control Centers’ Toxic Surveillance System, 4109 reported sulfonylurea exposures, with 38 major outcomes and 1 death, occurred in 2009. The incidence of hypoglycemia secondary to these agents rises in older patients and with long-acting agents (e.g., chlorpropamide). Consequently, independent risk factors for hypoglycemia include recent hospitalization, advanced age, and polypharmacy. Other risk factors for sulfonylurea-induced hypoglycemia are hepatic and renal dysfunction because of decreased metabolism (e.g., glyburide, glibenclamide, glipizide) and decreased elimination (e.g., chlorpropamide, glyburide). The most commonly used sulfonylureas have a duration of effect of at least 24 hours, and hypoglycemia in a patient taking such an agent can be prolonged, especially in the setting of overdose. In one case report, sulfonylurea-induced hypoglycemia was reported to last up to 27 days. Most other oral agents (e.g., thiazolidinediones, biguanides) used for the treatment of DM do not usually cause significant hypoglycemia.

Hypoglycemia is a simple diagnosis to make, provided it is considered early in a patient’s presentation. In most cases, hypoglycemia is considered in a patient with altered sensorium or depressed mental status. Bedside blood glucose testing using a glucose meter in the patient with neuroglycopenic symptoms is generally the fastest technique, as well as a fairly reliable method, to determine hypoglycemia. In general, the correlation of capillary blood glucose levels (which are measured by a glucose meter) with venous or arterial glucose measurements seems to be good. At extreme values (either high or low) and in cases of systemic hypoperfusion, however, a clinically significant discrepancy may be apparent. In the setting of suspected hypoglycemia, confirmatory laboratory testing of a serum specimen is therefore necessary. Furthermore, because symptoms of hypoglycemia vary among individuals, hypoglycemia is still a possible diagnosis even in a patient with a glucose level categorized as euglycemic.

Additional diagnostic testing may be necessary, depending on the clinical situation. For most patients with DM who present with hypoglycemia, routine testing of liver and renal function is indicated. Ethanol (or other alcohol) ingestion may also result in hypoglycemia, and measurement of serum ethanol concentration may be useful in the setting of alcohol intoxication. Other tests that may be helpful are thyroid function tests and measurements of serum cortisol, insulin, and C peptide concentrations. Insulin and C peptide measurements are particularly useful in the setting of surreptitious exposure to insulin or sulfonylureas. Unlike endogenous insulin synthesized by the pancreas, exogenous insulin has no concomitant C peptide. In cases of intentional insulin poisoning, insulin concentrations are high, but C peptide concentrations are normal. On the contrary, sulfonylurea ingestions cause elevations in both insulin and C peptide, the same findings as in patients with insulinoma. Finally, in patients with intentional self-harm, testing of serum acetaminophen concentration is potentially useful.

**TREATMENT**

The emergency physician must institute basic supportive measures, with particular attention to airway, breathing, and circulation, along with cardiorespiratory monitoring on encountering the obtunded patient with hypoglycemia (Box 156.2 has a treatment summary). Supplemental oxygen, intravenous (IV) thiamine, and naloxone are generally benign therapies that may be judiciously administered in a patient with depressed mental status of unknown origin.

After the primary survey has been performed and any needed measures taken, gastrointestinal decontamination should be considered for patients who have taken an intentional oral overdose of a hypoglycemic agent. The particular modality of decontamination implemented depends on the usual factors, such as time of ingestion, quantity of tablets, mental status of the patient, and potential harm to the patient. Activated charcoal has been shown to be very effective in binding to multiple sulfonylurea agents in vitro. A single dose of activated charcoal may be beneficial in these ingestions. In theory, multiple-dose activated charcoal may enhance elimination of the sulfonylurea glipizide because glipizide undergoes enterohepatic circulation.

**BOX 156.2 Treatment of Hypoglycemic Agent Overdose**

1. Basic support measures with attention to airway, breathing, circulation, and cardiopulmonary monitoring
2. Bedside glucose testing and an immediate bolus of glucose; hypoglycemia treated with IV glucose for severe episodes and when associated with obtundation: 0.5-1 g/kg of D_50W for adults and of D_25W for children
3. Consideration of thiamine and naloxone for obtunded patients
4. After initial euglycemia, continuous IV infusions of dextrose (D_5W or D_10W) started and boluses repeated when indicated
5. Decontamination with activated charcoal, either a single dose or multiple doses, for agents such as glipizide (enterohepatic circulation)
6. Enhanced elimination with IV sodium bicarbonate to alkalize urine and reduce the half-life for long-acting sulfonylureas (e.g., chlorpropamide)
7. Observation and admission for signs of neuroglycopenia and repeated serum glucose checks every 1 to 2 hr; monitoring of serum electrolyte levels every 4 hr
8. Octreotide, 50 mcg given subcutaneously every 6 to 8 hr, for at least 24 hr, in cases of prolonged hypoglycemia secondary to long-acting sulfonylurea overdose

\[D_{50W}, D_{25W}, W_{50}, W_{25}, 5\%, 10\%, 25\%, \text{and } 50\% \text{ dextrose in water, respectively; } IV, \text{ intravenous.} \]
patient should be given additional nutrition in the form of a snack or meal for a sustained source of calories. If the patient does not show response to oral carbohydrates, parenteral therapy is required.

IV dextrose is the preferred treatment for severe hypoglycemia with obtundation and a patient’s inability to take oral carbohydrates. The administration of 0.5 to 1 g/kg of IV dextrose rapidly reverses the clinical effects of hypoglycemia. Hypertonic dextrose solutions are commonly found in syringes containing 50 mL of 50% dextrose in water (D₅W), which is equivalent to 25 g of dextrose (4 calories/g of glucose or 100 calories). An average man weighing 70 kg would therefore require 35 to 70 g of dextrose. Administration of hypertonic dextrose is fairly safe, and only a few cases of significant adverse effects such as seizures, hypersomolar coma, and death have been reported. A much more common effect is phlebitis, which can be mitigated by injection of the dextrose into a large vein, followed by a saline flush.

After initial euglycemia is achieved, patients should be given continuous IV infusions of dextrose. Dextrose-water solutions of 5% (D₅W) and 10% (D₁₀W) are usually used in this setting, and the dose is titrated along with other therapies to maintain euglycemia. For patients with repeated episodes of hypoglycemia, higher concentrations of dextrose and repeated boluses of D₅W may be required. In this setting, hypertonic dextrose solutions should be administered by central line access because of the irritant venous effects of these solutions.

Treatment of overdose with a specific hypoglycemic agent depends on the agent. Some hypoglycemic agents, such as the meglitinides, are very short-acting drugs, and the resulting hypoglycemia is unlikely to be prolonged. For longer-acting insulins and the sulfonylureas, intensive therapy may be necessary for 1 or 2 days or even longer. The previously described approach to management is a general guideline to patients with hypoglycemia. Regardless of the cause of the hypoglycemia, patients should be frequently observed for signs of neuroglycopenia, bedside glucose checks should be performed every 1 to 2 hours at a minimum, and serum electrolyte levels should be monitored every 4 hours. Some patients may also require specific antidotal therapy, as described later.

Glucagon may also be administered by the subcutaneous, intramuscular, or IV route to stimulate hepatic glycogenolysis. Glucagon is most beneficial if it is given soon after the onset of hypoglycemic coma and to treat hypoglycemia in type 1 DM. Glucagon is less effective in patients with type 2 DM because it causes the release of insulin. These patients are also likely to already have depleted glycogen stores, thus limiting the efficacy of glucagon. Furthermore, glucagon administration may cause nausea and vomiting, which impair the ability to give oral carbohydrate therapy. Hypertonic IV dextrose is therefore the preferred initial therapy in the setting of acute hypoglycemia.

In patients with sulfonylurea-induced hypoglycemia, the same supportive measures as previously described are initially implemented. Occasionally, prolonged hypoglycemia may occur after a sulfonylurea overdose, especially with the long-acting agents. Antidotal therapy with octreotide should be considered in such refractory cases. A synthetic somatostatin analogue, octreotide inhibits the secretion of several neuropeptides, including insulin, and it is used clinically to suppress excessive growth hormone secretion, inhibit thyrotropin-secreting pituitary adenomas, and treat certain gastrointestinal and pancreatic neuroendocrine tumors (e.g., carcinoid insulinsomas).

Previously, the antihypertensive diazoxide was the recommended agent of choice for refractory hypoglycemia resulting from a sulfonylurea because of its ability to inhibit insulin secretion by opening adenosine triphosphate (ATP)–sensitive potassium (K_ATP) channels in pancreatic beta-islet cells. Although the use of octreotide for sulfonylurea-induced hypoglycemia is “off label” (i.e., the agent has not been approved by the U.S. Food and Drug Administration for this purpose), multiple case reports and research document its efficacy and safety. On the contrary, diazoxide has been shown to be less effective and has several undesirable properties. Diazoxide is usually administered by IV infusion, and its efficacy is limited in these situations because of associated hypotension, tachycardia, nausea, and vomiting. Adverse effects associated with octreotide are minimally significant; they include pain at the injection site, nausea, bloating, flatulence, diarrhea, and constipation. For these reasons, octreotide has supplanted diazoxide as the treatment of choice for sulfonylurea-induced hypoglycemia.

Octreotide has an IV half-life of 72 minutes, but when administered subcutaneously, it appears to be effective for approximately 6 hours. Consequently, a reasonable dosing scheme for most sulfonylurea agents would be 50 mcg subcutaneously every 8 to 12 hours (one noted textbook recommends every 6 hours) for at least 24 hours. After the octreotide is discontinued, an observation period for repetition of hypoglycemia is warranted for a minimum of 12 to 24 hours.

**TIPS AND TRICKS**

- Ill-appearing patients may have sepsis, chronic liver or renal failure, endocrinopathy resulting in deficiencies of cortisol or thyroid hormone, or acute-on-chronic alcohol abuse superimposed on chronic liver disease, with or without a state of chronic malnutrition.
- Hypoglycemia should be presumed to be present in all patients presenting to the emergency department with altered mental or psychiatric status, and hypoglycemia should be expeditiously excluded by rapid bedside glucose testing.
- For overdose with longer-acting insulins and the sulfonylureas, intensive therapy may be necessary for 1 or 2 days or even longer.
- Although the use of octreotide for sulfonylurea-induced hypoglycemia is “off label,” multiple case reports and research document its efficacy and safety. On the contrary, diazoxide has been shown to be less effective and has several undesirable properties.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

The decision to admit patients after an episode of hypoglycemia is multifactorial and in all cases depends on the cause.
Patients with systemic conditions, such as sepsis, hepatic or renal failure, drug-induced hypoglycemia, hypoglycemia of unknown origin, and persistent neurologic signs and symptoms, usually require admission. Patients who present with overdoses (unintentional or intentional) of insulin, sulfonylureas, and meglitinides need inpatient observation because of the unpredictable kinetics of these agents in this setting. For patients with DM in whom hypoglycemia develops despite therapeutic dosing and without a history of an overdose, admission depends on the expected duration of effect of the drugs, the severity and recurrence of hypoglycemia, and other possible toxic effects. Because most commonly used sulfonylureas have a duration of effect of at least 24 hours, admission is warranted even for a single episode of hypoglycemia, even though in theory it may be possible to observe these patients closely at home. Discharge is possible for patients with hypoglycemia if the likelihood of recurrence is minimal or the patient has a simple explanation for the episode of hypoglycemia (e.g., a missed meal). In patients who do not require any treatment with glucose, observation for 8 hours may be considered. In all patients with hypoglycemia, the emergency physician should err on the side of caution and exercise good clinical judgment when deciding on disposition.

Patients who are discharged home from the ED must be educated on frequent home glucose monitoring, and they should be instructed to obtain rapid follow-up with their primary care physician. Educating patients on warning signs and symptoms of hypoglycemia is crucial to prevent severe episodes from recurring.

Complications associated with hypoglycemia may be severe and include death. Myocardial infarction, cardiac dysrhythmias (e.g., QT prolongation, increased QT dispersion, ectopy, sudden bradycardia) and seizures may all occur. In the long term, neuroglycopenia may cause neurologic dysfunction and subsequent irreversible brain injury in patients with profound and prolonged hypoglycemia. Even in mild cases of hypoglycemia, long-term neurologic dysfunction may occur.

The prognosis of most patients with drug-induced hypoglycemia should be good, provided the diagnosis is promptly made and immediate therapy is instituted. The major pitfall in the treatment of hypoglycemia is usually the failure to make the diagnosis, by attributing the patient’s symptoms to some other condition (e.g., stroke, acute psychosis). Other pitfalls include failure to perform frequent glucose checks and underestimation of the pharmacokinetics or toxicokinetics of the specific agent involved. Consultation with the regional poison control center or with a local medical toxicologist may be of assistance in the management of these cases.

Over-the-Counter Medications

Stephen Thornton and Binh T. Ly

KEY POINTS

- Acetaminophen poisoning should be considered in patients presenting with over-the-counter medication misuse or overdose.
- Poisonings with antihistamine medications may manifest with antimuscarinic toxicity and sedation, but cardiac toxicity and seizures are also possible.
- Treatment for antihistamine poisoning is supportive care, but sodium bicarbonate and physostigmine may be helpful adjuncts.
- Dextromethorphan poisoning manifests as sedation, movement disturbances, and psychoactive dysphoria. Most of these effects are mediated by N-methyl-d-aspartate, rather than by opioid receptor activity.
- In overdose, poisoning with oral amphetamine-like decongestants may manifest as a sympathomimetic toxidrome.
- Imidazoline ocular and nasal decongestants such as oxymetazoline (Afrin) tetrahydrozoline (Visine), and naphazoline (Naphcon) may cause significant sedation when they are ingested orally.
- Diphenoxylate (Lomotil) can cause recurrent and delayed respiratory depression.
- Dietary supplements are mostly safe but are unregulated. Common conditions leading to poisoning include mislabeling, variations in concentration, contamination with unintended agents, and intentional adulteration.
- Vitamin A toxicity may cause increased intracranial pressure with associated symptoms.
- Vitamin D toxicity may cause significant hypercalcemia.

ANTIHISTAMINES

EPIDEMIOLOGY

Antihistamines are among the most frequently used medications in the United States. Most of these drugs are available without a prescription. Although their efficacy is questionable, antihistamines are widely used for the symptomatic relief of cold and allergy symptoms. They are also found in nonprescription sleeping aids. Because of widespread access, these agents are commonly ingested intentionally, in suicide attempts, and unintentionally, particularly by children. Approximately 90,000 cases of antihistamine ingestions are reported to poison centers in the United States every year, and almost half of those involve children younger than 6 years.

PATHOPHYSIOLOGY

The antihistamines function as reversible competitive inhibitors of either H1 or H2 histamine receptors. Currently available antihistamines can be classified as first-generation, sedating H1 receptor antagonists (e.g., diphenhydramine, hydroxyzine); second-generation, nonsedating H1 receptor antagonists (e.g., loratadine, fexofenadine); or H2 receptor antagonists. Antagonism of the H1 receptors inhibits bronchoconstriction, vascular constriction, and capillary permeability (the cause of edema and wheal), whereas H2 receptor antagonism inhibits gastric acid secretion. In overdose, first-generation H1 receptor antagonists may have some additional effects on other receptors and ion channels, particularly muscarinic-type cholinergic receptor inhibition, α-adrenergic receptor inhibition, and fast sodium channel blockade, whereas second-generation H1 receptor blockers and H2 receptor antagonists primarily cause sedation.

PRESENTING SIGNS AND SYMPTOMS

Patients typically present with some degree of altered mental status or suicidality. A history of ingestion or coingestions should be sought. Emergency medical personnel and family members, if available, may need to be questioned. Pill bottles, if present, may help clarify the history.

Although sedation is common with larger ingestions, signs of antimuscarinic toxicity may also be present. In addition, patients may have mild hypotension or more worrisome wide complex dysrhythmia resulting from sodium channel–blocking effects of some antihistamines (e.g., diphenhydramine). Cardiovascular toxicity associated with some antihistamines is indistinguishable from that associated with cyclic antidepressants.
Over-the-Counter Medications

processes can cause a presentation characterized by sedation or delirium, or both (Box 157.2). The emergency physician must consider nontoxicologic causes of altered mental status, such as infection and traumatic brain injury, and evaluate for these nontoxicologic conditions accordingly if the presence of the conditions cannot be excluded by other means. Computed tomography of the head and lumbar puncture may be warranted. In particular, patients presenting with antimuscarinic toxicity may be delirious, hyperthermic, and tachycardic, features that mimic infectious causes.

Bedside blood glucose measurements should be performed early in the course of management for individuals presenting with altered sensorium. An electrocardiogram should be obtained quickly to assess for conduction abnormalities, with particular attention paid to the QRS and QTc duration. Serum electrolyte concentrations should be measured to rule out metabolic abnormalities in patients who are confused or who exhibit evidence of cardiotoxicity. Laboratory evaluation of total creatinine kinase to evaluate for rhabdomyolysis may be indicated in acutely agitated patients. Serum acetaminophen levels should be measured in all patients with intentional overdose, because many cough and cold preparations combine antihistamines with antipyretics and analgesics. A urine

**DELIRIUM/AGITATION**
- Agitation without violence distinguishes this from sympathomimetic toxicity
- Mumbling that almost sounds intelligible
- Picking behavior at real objects (buttons, your stethoscope) or imaginary ones
- MANAGEMENT: lorazepam, physostigmine, restraints as needed; avoid haloperidol, which can worsen symptoms

**ANHIDROSIS**
- Check axilla for lack of moisture
- Distinguishes anticholinergic (dry) from sympathomimetic

**URINARY RETENTION**
- Maintain high clinical suspicion
- Place Foley catheter if suspected
- Residual urine of more than 200-300 mL makes the diagnosis in the patient with altered mental status
- MANAGEMENT: Catheterization

**MYDRIASIS**
- Shared feature with sympathomimetic poisoning
- Pupils > 5 mm in normal ED lighting

**TACHYCARDIA/CONDUCTION DELAYS**
- May be absent even in the presence of central toxicity (delirium)
- MANAGEMENT: no treatment if normotensive; IV fluids and norepinephrine if hypotension is intractable; sodium bicarbonate for conduction delays

**HYPERTHERMIA**
- Caused by anhidrosis and impaired evaporative cooling
- Can be subtle or extreme
- Always check rectal temperatures
- MANAGEMENT: Active cooling with misting and fanning, IV fluids

immunoassay (standard urine drugs of abuse screen) may be considered to screen for recent exposure to opioids, benzodiazepines, or other drugs, although the clinical utility of this test is limited by frequent false-positive results. The emergency physician should recognize that a positive screening test result indicates only exposure to and not active toxicity of a compound. Qualitative testing for antihistamines is not useful and generally not readily available. Diphenhydramine may trigger a false-positive immunoassay result for tricyclic antidepressants or phencyclidine (PCP) on some urine drug immunoassays typically used in many hospitals.

**TREATMENT**

Prehospital treatment of the acutely poisoned patient should be based on providing supportive care and preventing complications such as injury from agitation or aspiration from decreased mental status.

Hospital treatment should also be focused on supportive care with assessment of airway, breathing, and circulation. Particular attention should be paid to controlling agitation and hydration (Table 157.1). Agitation should be treated with benzodiazepines in doses titrated to desired effect (e.g., lorazepam, 1 to 2 mg by intravenous [IV] push to effect). In addition to chemical restraint, physical restraint for patient and staff safety may be needed. Hydration should be addressed with 1- to 2-L boluses of 0.9% saline solution to ensure adequate urine output.

In patients who present within 1 hour of drug ingestion and who are alert and cooperative, activated charcoal (50 g or 1 g/kg up to 50 g in children) should be considered. Data in humans are insufficient to support the use of activated charcoal beyond 1 hour.³

Hyperthermia should be managed with sedation and active, evaporative cooling (misting with water and applying direct fanning). Rarely, endotracheal intubation with neuromuscular paralysis may be necessary if hyperthermia or agitation fails to improve with less aggressive measures.

Physostigmine is a reversible acetylcholinesterase inhibitor that crosses the blood-brain barrier; it increases synaptic acetylcholine and may temporarily reverse antimuscarinic delirium. Peripheral signs may also be reversed. It may also be used therapeutically to control agitation. Physostigmine may have more value as a diagnostic tool by precluding the need for invasive tests (e.g., lumbar puncture) if complete reversal of delirium is achieved following administration. Beyond diagnostic use, the role of physostigmine in the treatment of most antimuscarinic poisonings with minor symptoms is debatable, and caution should be used if a possibility of tricyclic antidepressant ingestion exists.

Severe cardiac conduction abnormalities as evidenced by QRS prolongation should be treated with sodium bicarbonate (1 to 2 mEq/kg IV push) to overcome impaired sodium conduction. Hypotension is usually mild and should be treated with IV fluids. Refractory hypotension may also be treated with sodium bicarbonate and direct-acting alpha-agonists (norepinephrine, 2 to 12 mcg/min IV infusion).

As with all ingestions with significant toxicity, consultation with a medical toxicologist or a poison center should be considered.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with evidence of ongoing cardiovascular or neurologic toxicity should be admitted. Completely asymptomatic patients who have been observed for 6 hours after drug ingestion may be medically cleared for psychiatric evaluation or discharged, whichever is most appropriate.

**ANTITUSSIVES: DEXTROMETHORPHAN**

**EPIDEMIOLOGY**

Dextromethorphan was approved by the U.S. Food and Drug Administration (FDA) as an over-the-counter antitussive in 1958. It is a common component of cold preparations, and its nonmedical use (abuse) appears to be increasing, especially among adolescents. Abuse of Coricidin (known on the streets as “Skittles”) and Robitussin (known as “DXM” and “robo”) has highlighted dextromethorphan’s abusive potential.

**PATHOPHYSIOLOGY**

Dextromethorphan is the structural analogue of the opioid analgesic levorphanol that is devoid of analgesic properties but has antitussive properties resulting from agonism of σ-opioid receptors. In addition, dextromethorphan inhibits N-methyl-D-aspartate (NMDA)–glutamate receptors and alters dopaminergic and serotonergic neurotransmission. Associated psychoactive effects are attributed to the active metabolite dextrorphan. At very high doses, typical opioid toxicity may be seen.

**PRESENTING SIGNS AND SYMPTOMS**

Some degree of altered mental status (sedation or agitation) is the most common presenting manifestation. This feature may impair the ability to obtain a reliable history from the patient, and emergency medical personnel or family may need to be questioned.

Along with altered mental status, dextromethorphan may cause gait disturbances known as “robo-walking.” Serotonin syndrome, which consists of a triad of central nervous system (CNS) dysfunction, neuromuscular dysfunction (clonus, hyperreflexia), and autonomic instability (tachycardia, mild hyperthermia), may also be noted in patients with toxicity.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The initial approach to patients with altered mental status includes ruling out potential emergency conditions such as trauma, CNS infection, and metabolic derangements. Other common CNS depressants, such as benzodiazepines, opioids, and ethanol, may also cause sedation. Recreational drugs of abuse with similar actions at the NMDA receptor, such as PCP and ketamine, may also cause dysphoria and psychoactive features. Antimuscarinic poisoning does not result from dextromethorphan poisoning but can occur from coingested antihistamines such as chlorpheniramine (as found in Coricidin).

Although structurally considered an opioid, dextromethorphan does not trigger the opiate screen on a standard urine immunoassay, but it may result in a false-positive result for PCP. Dextromethorphan is often formulated as a hydrobromide salt; ingestions of such a formulation may cause false elevations of chloride on an autoanalyzer test, although true toxicity from bromide is rare.

Emergency physicians should be mindful of potential coingestants because many cough and cold preparations frequently contain aspirin, acetaminophen, decongestants, and antihistamines. Acetaminophen levels should be routinely checked in poisoned patients.

**TREATMENT**

Prehospital treatment of the acutely poisoned patient should be based on providing supportive care and preventing complications such as injury from agitation or aspiration from decreased mental status.

Hospital treatment should be focused on supportive care with assessment of airway, breathing, and circulation. Attention should be paid to controlling agitation and hydration. Agitation should be treated with benzodiazepines in doses titrated to effect (IV lorazepam, 1 to 2 mg titrated to effect) (see Table 157.1). Reducing environmental stimuli may also be helpful. In addition to chemical restraint, physical restraint for patient and staff safety may be needed. Hydration should

Agitation should be treated with benzodiazepines in doses titrated to effect (IV lorazepam, 1 to 2 mg titrated to effect) (see Table 157.1). Reducing environmental stimuli may also be helpful. In addition to chemical restraint, physical restraint for patient and staff safety may be needed. Hydration should
Supportive care is the treatment of choice. IV naloxone (1 to 10 mg) may be given for significant sedation, although reversal may not occur.\textsuperscript{7} Patients with evidence of ongoing neurologic toxicity should be admitted. Completely asymptomatic patients who have been observed for 6 hours after drug ingestion should be evaluated by a psychiatrist to determine whether admission is indicated.

Patients with evidence of ongoing neurologic toxicity should be admitted. Completely asymptomatic patients who have been observed for 6 hours after drug ingestion should be evaluated by a psychiatrist to determine whether admission is indicated.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with evidence of ongoing neurologic toxicity should be admitted. Completely asymptomatic patients who have been observed for 6 hours after drug ingestion should be evaluated by a psychiatrist to determine whether admission is indicated.

**DECONGESTANTS:**

**PSEUDOEPHEDRINE, EPHEDRINE, PHENYLEPHRINE, OXYMETAZOLINE, AND TETRAHYDROZOLINE**

Over-the-counter decongestants rank among the top five most commonly used medications.\textsuperscript{1} They are frequently present in multiple ingredient cough and cold products. Some are abused for their stimulatory effects or diverted for the production of methamphetamines. As with other over-the-counter medications, children are frequent victims of unintentional poisonings or dosing errors, and decongestant exposure in this population has been linked to adverse outcomes.\textsuperscript{2}

**EPIDEMIOLOGY**

Over-the-counter decongestants rank among the top five most commonly used medications.\textsuperscript{1} They are frequently present in multiple ingredient cough and cold products. Some are abused for their stimulatory effects or diverted for the production of methamphetamines. As with other over-the-counter medications, children are frequent victims of unintentional poisonings or dosing errors, and decongestant exposure in this population has been linked to adverse outcomes.\textsuperscript{2}

**PATHOPHYSIOLOGY**

Over-the-counter decongestants have their therapeutic effects primarily by stimulating $\alpha_{1}$-adrenergic receptors and causing vasoconstriction and reducing edema in mucous membranes. They fall into two main classes. This first class is amphetamine-like substances (e.g., pseudoephedrine, ephedrine, phenylephrine), which cause release of catecholamines, and block their reuptake and breakdown and are taken orally. The other class is imidazoline decongestants (e.g., oxymetazoline, tetrahydrozoline, naphazoline), which directly stimulate $\alpha$-adrenergic receptors on blood vessels and are applied topically.

**PRESENTING SIGNS AND SYMPTOMS**

The presenting signs and symptoms from the ingestion of over-the-counter decongestants will vary depending on the class ingested (see Table 157.1). Ingestion of an amphetamine-like decongestant typically presents signs and symptoms of sympathomimetic toxicity due to the increased stimulation of both $\alpha$- and $\beta$-adrenergic receptors. This is typified by agitation, delirium, tachycardia, hypertension, hyperthermia, and mydriasis. Ingestion of imidazolines, which are meant for topical use, usually presents with sedation, bradycardia and hypertension early with subsequent hypotension. Respiratory depression, sedation, and miosis, mimicking opioid toxicity, have been described.\textsuperscript{10}

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

If the history of ingestion is not clear then the differential diagnosis for decongestant ingestions can be broad, especially considering the disparate presentations of the amphetamine-like and the imidazoline classes (see Table 157.1). Coingestions and nontoxicologic processes must be considered. Rhabdomyolysis and cardiac ischemia should be evaluated for in patients with significant toxicity.

**TREATMENT**

Standard prehospital care should be sufficient for decongestant-toxic patients, with particular attention paid to controlling agitation. Decontamination with activated charcoal is suitable for the alert patient with exposure in the previous hour. Agitation, tachycardia, and hypertension should be aggressively treated with benzodiazepines (IV lorazepam, 1 to 2 mg, or IV diazepam, 5 to 10 mg, titrated to effect). The physician must aggressively hydrate these patients to treat rhabdomyolysis. For refractory hypertension, an $\alpha$-adrenergic antagonist (IV phentolamine, 5 mg) or a venous and arteriolar vasodilator (IV nitroprusside, 0.3 to 10 mcg/kg/min) should be given. In severe cases of CNS depression after imidazoline-type decongestant overdose, IV naloxone may be given (2 to 4 mg) but its effects are inconsistent, and endotracheal intubation may rarely be needed to support ventilation.\textsuperscript{11}

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Symptoms of decongestant exposure, whether amphetamine-like or imidazoline, usually resolve within 8 hours or so. However, admission of symptomatic patients may be warranted. Depending on intent, psychiatry evaluation may be needed.

**ANTIDIARRHEALS:**

**LOPERAMIDE AND DIPHENOXYLATE**

**EPIDEMIOLOGY**

Diarrhea remains an important and frequent health problem. Over-the-counter remedies are often sought by diarrhea sufferers, and many different over-the-counter agents are reported to be antidiarrheal. Loperamide (Imodium) is probably the best known of these agents. Diphenoxylate with atropine.
(Lomotil) is a prescription medication and frequently used interchangeably with loperamide.

**PATHOPHYSIOLOGY**

Loperamide and diphenoxylate are synthetic analogues of meperidine used to treat diarrhea. Loperamide's systemic absorption is restricted by its insolubility, and therapeutically only local μ-type opioid receptors in the gastrointestinal tract are affected, resulting in decreased intestinal motility. Diphenoxylate is combined with a small dose of atropine both to increase its antimitoty effect and to discourage its abuse as an opioid (this combination is marketed as Lomotil). Diphenoxylate has a significantly worse adverse effect profile because it metabolizes to difenoxin, a compound with higher potency and a longer serum half-life.

**PRESENTING SIGNS AND SYMPTOMS**

Loperamide is generally well tolerated even in large ingestions, and drowsiness is the most common effect. Diphenoxylate is significantly more toxic, and overdoses commonly manifest with some degree of opioid toxicity (e.g., CNS depression, respiratory depression, miosis, decreased bowel motility), with or without the antimuscarinic effects of the atropine (see Table 157.1).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis includes conditions that cause altered mental status and respiratory depression. No specific tests are available to order in evaluating these patients. Common urine drug screens do not detect either drug. Any diagnostic tests ordered should be geared toward the standard evaluation of the poisoned or altered patient and not these agents in particular.

**TREATMENT AND DISPOSITION**

Prehospital treatment should be oriented toward providing supportive care and preventing complications such as aspiration from decreased mental status. Prehospital administration of naloxone may be considered.

In general, loperamide has a high safety profile and has been associated with very few adverse events, even in overdose. However, diphenoxylate overdoses can cause significant symptoms, usually related to respiratory depression (see Table 157.1). Respiratory depression by can be recurrent or delayed, sometimes up to 24 hours after the ingestion, and children are particularly at risk. Decontamination with activated charcoal in the cooperative patient may be useful even beyond the 1 hour, given the impairment of gastrointestinal motility with these agents. IV naloxone (0.4 to 2.0 mg) is effective in reversing the respiratory depression and other signs of opioid toxicity, but CNS and respiratory depression may recur, and an IV naloxone infusion may be needed.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with loperamide ingestions can typically be observed for 6 hours and medically cleared for psychiatric evaluation if the ingestion was intentional or discharged if unintentional. Strong consideration should be given to admitting pediatric patients and patients with intentional and significant Lomotil ingestions because of the possibility of severe delayed or recurrent symptoms (e.g., respiratory depression).

**DIETARY SUPPLEMENTS**

**EPIDEMIOLOGY**

Any ingredient taken for the purpose of promoting health is considered a dietary supplement. Innumerable examples of dietary supplements exist, and a national surveyed showed that more than 15% of the U.S. population had used one or more in the previous week. Ginkgo, St. John’s wort, ginseng, echinacea, and synephrine are among the more commonly used dietary supplements (Table 157.2). Unlike with prescription drugs, proof of safety and proof of efficacy are not required for dietary supplements as long as the maker does not claim that the agent is a treatment for a particular disease. To be removed from the market, a dietary supplement must be proven unsafe. This situation occurred in 2006, when the FDA banned of ephedra over cardiovascular concerns.

**PATHOPHYSIOLOGY**

The exact mechanism of action of many of the dietary supplements is poorly understood. Severe toxicity from most supplements remains uncommon because of the low concentrations of specific agents in marketed products. Toxicity may arise not only from the product itself but also from unlisted active ingredients and from contaminants such as heavy metals. Supplements may also have interactions with certain drugs that affect metabolism and efficacy.

**PRESENTING SIGNS AND SYMPTOMS**

Depending on the specific dietary supplement, presenting signs and symptoms vary. Table 157-2 lists some of the possible toxic manifestations of the more common dietary supplements.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis is driven by the particular supplement ingested. For example, ingestion of an ephedra-like supplement (bitter orange) suggests other causes of sympathomimetic toxicity such as cocaine and amphetamines. No diagnostic testing is specific to dietary supplements, and drug levels are of no value.

TREATMENT

Dietary supplement exposures pose unique challenges because of the lack of information on the toxicologic profiles, pharmacokinetics, and concentrations of their active ingredients. Most cases of toxicity stemming from therapeutic use can be managed with supportive care and symptom-based therapy.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Symptomatic patients should be admitted for observation and symptomatic therapy. A psychiatric consultation should be obtained when warranted. Patients who are asymptomatic 4 to 6 hours after an acute accidental overdose of a known agent with known safety profiles can be discharged with appropriate follow-up.

VITAMINS

EPIDEMIOLOGY

Vitamins are frequently taken in supratherapeutic amounts. This is done typically under the premise of “more is better” or purportedly to treat or prevent conditions ranging from viral upper respiratory tract infections to Alzheimer dementia.

Parents’ concern about their children’s eating patterns may result in vitamin oversupplementation. All these factors, added to the ready availability of vitamins, make vitamins prime targets for potential toxic exposures.

PATHOPHYSIOLOGY

Vitamins can be grouped into two main categories: water soluble and fat soluble. Toxicity may be caused by either group, though in general toxicity from water-soluble vitamins are rarer and less severe as they do not accumulate as fat-soluble vitamins do. Vitamin A and D, which are both fat soluble, have well described toxicity. Table 157.3 describes the normal function of the most common vitamins and their toxic effects.

PRESENTING SIGNS AND SYMPTOMS

The presenting signs and symptoms of hypervitaminosis depend on the offending vitamin. Table 157.3 lists the toxic effects of the most clinically relevant vitamins.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Because of the relative infrequency of severe toxicity from hypervitaminosis, the more common causes of such conditions as sensory neuropathies, increased intracranial pressure,
and hypercalcemia must be explored first. The diagnosis of a vitamin overdose is most often made from a history of ingestion. In patients with vitamin A toxicity, elevations of amino-transferase, alkaline phosphatase, and bilirubin concentrations, as well as prothrombin time, are indicators of hepatic toxicity. Computed tomography of the head or lumbar puncture with measurement of the opening pressure should be performed to confirm increased intracranial pressure. Vitamin D toxicity can be demonstrated with elevated calcium and vitamin D levels. Because many vitamin preparations contain iron or fluoride, these agents must be considered and evaluated as possible coingestants.

## TREATMENT

Typically, supportive care and cessation of the offending vitamin are sufficient to treat most vitamin toxicities. In the case of vitamin A toxicity, measures to reduce intracranial pressure may be warranted, and in the case of vitamin D
SECTION XV  TOXICOLOGIC EMERGENCIES

toxicity, standard treatment for hypercalcemia (IV hydration and loop diuretics) should be employed (see Table 157.3).

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients who are toxic from fat-soluble vitamin overdoses typically need admission because the effects of these agents may be prolonged. All patients should be educated on the risk of hypervitaminosis.

Pediatric Overdoses
Shana Kusin and Patrick M. Lank

Pediatric exposures to toxic substances represent the majority of cases reported to poison centers in the United States. Children less than 5 years old accounted for 52%, or 1.29 million, of total reported exposures in 2009. In contrast, exposure-related fatalities in the same age group represented only 1.8%, or 21, of total fatalities in 2009, and 18 of these fatalities were classified as unintentional exposures.1 This finding reflects the fact that toxic exposure in the child younger than 5 years old is generally the result of an inquisitive toddler exploring his or her environment.

The “One Pill Can Kill” list refers to a group of agents that are known to cause serious toxicity or death when they are ingested in very small quantities by a small child (Box 158.1). The emergency physician must be familiar with these agents to manage these patients appropriately and to anticipate the potential for poor outcomes. Many of these agents are covered in more detail in other chapters in this section.

PATHOPHYSIOLOGY

OVER-THE-COUNTER AGENTS

Camphor
Camphor is an aromatic terpene ketone, originally distilled from the bark of the camphor tree and now synthesized from turpentine oil. It is a common ingredient in some topical and vaporized medications intended to treat musculoskeletal pain or symptoms of common flu-like illnesses (Table 158.1). Camphor is marketed as an analgesic, an antipruritic, and an antitussive, and it is also found in older formulations of mothballs.

The exact mechanism by which camphor produces toxicity is unknown, although the cyclic ketone of its hydroaromatic terpene group is hypothesized to be a neurotoxin. Camphor is highly lipophilic, resulting in rapid movement across cell membranes and a large volume of distribution. Its metabolites are stored in fat deposits and are cleared over a prolonged period of time, which may be responsible for the delayed onset of seizures associated with camphor toxicity.2 Camphor may also cause gastrointestinal toxicity from its direct effect on mucosal surfaces.

Doses between 750 and 1500 mg, and doses as low as 500 mg in some case reports, are associated with seizures and death.2 For this reason, the U.S. Food and Drug Administration ruled in 1982 that products could not contain more than 11% camphor. However, some commercially available formulations contain 500 mg in 1 teaspoonful of product. In addition, a case series of pediatric seizures attributed to camphor toxicity highlights the role that camphor still plays in some ethnic and cultural practices. Illegally sold, high-concentration camphor products pose a risk in these populations.3

Salicylates
Salicylates are present in numerous over-the-counter products and are marketed as analgesics, antipyretics, and antinflammatory agents (Table 158.2). Several Asian herbal remedies sold as topical treatments for musculoskeletal pain also contain salicylates.

Oil of wintergreen represents a specific concern in the pediatric population because of its extremely high concentration. One teaspoon of 98% oil of wintergreen contains 7000 mg of methylsalicylate, equivalent to 86 baby aspirin, a potentially lethal dose for children weighing less than 23 kg. This product has a pleasing aroma, thus rendering it
particularly vulnerable to accidental ingestion. A review of pediatric salicylate poisonings found that all published cases of life-threatening toxicity or death resulted from oil of wintergreen or Asian herbal oil ingestions.3

Salicylate toxicity is caused both by direct stimulation of the central nervous system (CNS) respiratory center, resulting in hyperventilation and respiratory alkalosis, and by uncoupling of oxidative phosphorylation, which results in anion gap metabolic acidosis. Pulmonary and cerebral edema is hypothesized to result from increased capillary permeability. Impaired glucose metabolism can lead to hyperglycemia or hypoglycemia. Doses greater than 150 mg/kg are potentially toxic in children, and serious toxicity is seen in the range of 300 to 500 mg/kg.

**Topical Anesthetics**

Topical anesthetics are found in various pain-relieving products ranging from teething gels to hemorrhoid creams (Table 158.3). Amide anesthetics, which include lidocaine and dibucaine, work by blocking voltage-gated sodium channels and preventing action potential propagation. In toxic doses, these agents can cause CNS hyperstimulation secondary to central blocking of inhibitory pathways that can progress to seizures, respiratory depression, and coma. Amides can also cause cardiac toxicity because of their antiarrhythmic properties, but this is most frequently seen in intravenous, rather than oral, exposures.5

Benzocaine is an ester anesthetic whose metabolites can cause methemoglobinemia in toxic doses. Methemoglobin is formed by oxidation of iron from the ferrous (Fe2+) to the ferric (Fe3+) state within the hemoglobin molecule. This process causes a leftward shift in the hemoglobin-oxygen dissociation curve and decreases hemoglobin’s oxygen carrying capacity. Patients less than 6 months old have a relative deficiency of methemoglobin reductase and may be more susceptible to toxicity.5

Prilocaine is an amide compound that has been shown to cause methemoglobinemia as its primary toxicity in overdose.5 Both prilocaine and lidocaine are components in EMLA cream, so this particular cream can cause either CNS toxicity or methemoglobinemia in overdose.

A literature review found published cases of seizures resulting after single ingestions of 5 to 25 mL of viscous lidocaine by children 2 years of age or younger.6 Although dibucaine is less commonly prescribed than lidocaine, it is 10 times more potent, and ingestion of 2 to 3 teaspoons has caused death secondary to cardiopulmonary arrest.6 Published reports of benzocaine-induced toxicity vary; cyanosis secondary to methemoglobinemia may result from oral doses in the range of 15 to 40 mg/kg, although the development of methemoglobinemia may be idiosyncratic, rather than dose related.

**CAUSTICS**

Many household products are caustic agents and can cause significant toxicity with small exposures. Caustic agents are classified as alkaline or acid corrosives, depending on their pH (Table 158.4). Passed in 1970, the Federal Hazardous Substances Act and the Poison Prevention Packaging Act stated that caustic agents with a concentration higher than 10% must be placed in child-resistant containers. By 1973, the household product concentration limit had been lowered to 2%.
Alkaline corrosives cause liquefaction necrosis, which is characterized by protein dissolution, collagen destruction, fat saponification, cell membrane emulsification, and cell death. Damage continues after surface exposure because of the ability of alkaline corrosives to penetrate tissue. In contrast, acids cause coagulation necrosis, which leads to desiccation of epithelial cells and produces eschar, with resulting edema, erythema, mucosal sloughing, ulceration, and necrosis of the surface tissues.

The dose of a caustic agent causing significant toxicity varies by product and concentration. Information on specific agents can be obtained from product packaging and from a poison control center.

**HYDROFLUORIC ACID**

Hydrofluoric acid and related compounds, such as ammonium bifluoride, ammonium fluoride, potassium bifluoride, and sodium bifluoride, are found in rust removers, automobile wheel cleaners, toilet bowl cleaners, air conditioner coil cleaners, dentifrices, and insecticides. The bifluorides can form hydrofluoric acid in the presence of body water and can thus cause delayed presentation of symptoms. The fluoride ion is directly toxic to numerous cellular enzymes and also forms complexes with calcium and magnesium. These complexes precipitate in tissues and cause significant pain and tissue destruction. At high enough levels of fluoride, these complexes can lead to systemic depletion of calcium and magnesium that can precipitate life-threatening arrhythmias.

The toxic ingested dose of hydrofluoric acid is between 5 and 10 mg/kg, and death occurs after a dose of 15 to 30 mg/kg. This translates into a lethal dose of 50 mg for a 10-kg child, a quantity contained in 5 mL of 10% hydrofluoric acid.

**CALCIUM CHANNEL BLOCKERS**

Calcium channel blockers are widely prescribed for their chronotropic and anti hypertensive effects. They exert their action through L-type voltage-gated channels present in cardiac myocytes, vascular smooth muscle, and the sinoatrial and atrioventricular nodes. The three main classes of calcium channel blockers are the phenylalkylamines, the benzothiapi-ринес, and the dihydropyridines. The phenylalkylamines (verapamil) and the benzothioprinсes (diltiazem) act predominantly on myocytes and cardiac tissue, and the dihydropyridines (nifedipine) work predominantly on vascular tissue. Bepridil, the sole agent representing a fourth class, is not in widespread use because of its poor side effect profile.

Calcium channel blocker overdose causes severe hypoten- sion and bradycardia, although reflex tachycardia may also be seen in overdose of the vascular tone–predominant dihydropyridines. Calcium channel blockade is responsible for dysrhythmias ranging from heart block to idioventricular arrhythmias. Impaired insulin release and systemic insulin resistance lead to the classic finding of hyperglycemia. Pulmonary edema may occur; the mechanism is unknown, but the edema may be caused by selective precapillary vasodila- 

**CLONIDINE AND TOPICAL IMIDAZOLINES**

Clonidine is a centrally acting α-receptor agonist that inhibits sympathetic pathways. It was developed in the 1960s as a nasal decongestant, but it is most commonly used as an anti hypertensive and in the treatment of narcotic and alcohol withdrawal, of perimenopausal hot flashes, and, more recently, in the treatment of pediatric attention-deficit hyperactivity disorder and Tourette disorder. Topical imidazolines are found in over-the-counter decongestants for the nose and eyes, including oxymetazoline (Afrin), naphazoline (Naphcon), xylometazoline (Otrivin Pediatric Nasal) and tetrahydrozoline (Visine).

The exact mechanism of clonidine toxicity is not fully understood. Because of functional overlap between α2 and μ receptors, symptoms of clonidine toxicity can mimic those of opioid toxicity. Peripheral α2-receptor stimulation may cause a transient period of hypertension before centrally mediated bradycardia and hypotension predominate. In con- trast to clonidine, the topical imidazolines are specifically designed to induce local α2-mediated peripheral vasoconstric- 

**CHAPTER 158 PEDIATRIC OVERDOSES**

Data on the minimum dose required to produce significant toxicity in children are mixed, but published cases have reported that one to two pills caused significant morbidity or death in children less than 6 years of age.

Calcium channel blocker overdose and beta-blocker over- dose are commonly discussed together in the adult literature because of their similarity of presentation and the therapeutic coadministration of these medications. A review of the pedi-atric literature found no published cases of death in young children as a result of accidental ingestion of beta-blockers, so these agents do not appear on the “One Pill Can Kill” list.

A minimum toxic dose of imidazoline has not been estab-

This translated into a lethal dose of 50 mg for a 10-kg child, a quantity contained in 5 mL of 10% hydrofluoric acid.
in case reports to cause altered mental status in children, which correlates with ingestion of a single 0.1-mg tablet by a 10-kg child. Larger doses have been associated with more severe symptoms.12

DIPHENOXYLATE-ATROPINE (LOMOTIL)
Diphenoxylate-atropine, most commonly known as Lomotil, is an antidiarrheal agent consisting of a combination of opioid and anticholinergic medications. Diphenoxylate, a meperidine derivative, decreases smooth muscle action of the gut. Atropine is added to decrease the drug’s abuse potential. Lomotil toxicity can be both prolonged and delayed, secondary to its combined opioid and anticholinergic effect on gut motility. Diphenoxylate’s primary metabolite, dexofenoxine, is more active and has a longer half-life than diphenoxylate and thus exacerbates the phenomenon of delayed presentation.

Lomotil has classically been included on most “One Pill Can Kill” lists, but one review of the literature revealed a paucity of data demonstrating that significant morbidity is caused by small doses.13 Most deaths are attributed to ingestion of multiple pills or repetitive, incorrect dosing over time. No established minimum toxic dose exists, but the review found no reports of significant toxicity with ingestions of fewer than six to eight tablets in small children.

SULFONYLUREAS
Sulfonylureas are used for the treatment of non–insulin-dependent diabetes mellitus and can cause significant hypoglycemia after the ingestion of one or two pills by young children. Examples are chlorpropamide, glyburide, glimepiride, glipizide, tolazamide, and toltubamide. Sulfonylureas lower blood glucose primarily by stimulating endogenous insulin secretion and secondarily by enhancing peripheral insulin receptor sensitivity and reducing glycogenolysis.

Death is rare with sulfonylurea exposure. Only one case was found in a literature review.14 However, many children less than 6 years old become symptomatic from sulfonylurea ingestion, and numerous case reports have noted symptoms in children who ingested one to two pills.

TRICYCLIC ANTIDEPRESSANTS
Tricyclic antidepressants (TCAs) represent a diverse group of medications that have been historically responsible for many poisoning deaths. In addition to their use in the treatment of depression, TCAs have been used to treat migraines, chronic pain, and enuresis, and they have been administered as second-line therapy for several pediatric psychiatric disorders.

TCA toxicity manifests primarily with cardiovascular and CNS effects. Inhibition of the fast sodium channel causes cardiac conduction disturbances, resulting in a widened QRS complex. Blockade of catecholamine reuptake can cause tachycardia and mild hypertension, although these effects are usually offset by peripheral α-adrenergic blockade causing vasodilation and hypotension. CNS effects of delirium, seizures, and coma are likely caused by anticholinergic effects, as well as by central blockade of neurotransmitter uptake. Anticholinergic effects can also slow gastric emptying and produce delayed or unpredictable absorption.

Several case reports published since the 1970s demonstrated that one or two pills can kill a small child. Significant morbidity or mortality tends to occur at doses greater than 15 to 30 mg/kg; ingestion of one or two 150-mg pills by a 10-kg toddler can easily reach this level.15

PRESENTING SIGNS AND SYMPTOMS

CAMPHOR
Camphor toxicity most often develops 5 to 90 minutes from the time of ingestion, but some case reports have noted presentations as late as 9 hours after ingestion.16 Clinical toxicity may first manifest with gastrointestinal complaints, from oral burning to nausea and vomiting. Initial CNS effects of hyperactivity such as irritability, hyperreflexia, and myoclonic jerking may progress to seizure, delirium, and coma. Seizures are common and may persist for up to 24 hours, although this does not seem to have prognostic implications.2 When death occurs, it is usually the result of status epilepticus or respiratory failure.

SALICYLATES
Patients may present with vomiting, hyperpnea, tinnitus, and a mixed metabolic picture of respiratory alkalosis and metabolic acidosis. In contrast to adults, children less than 2 years old tend to present with metabolic acidosis only, rather than the classic mixed picture, because respiratory alkalosis appears to be transient. Salicylate-induced hypoglycemia may also be more pronounced in children than in adults. More serious intoxications may progress to CNS symptoms, including lethargy, agitation, delirium, or seizures. Respiratory acidosis suggests pulmonary edema and fatigue. Hyperthermia reflects oxidative uncoupling and is often a preterminal finding.

Symptoms of oil of wintergreen ingestion may progress much faster than symptoms caused by other agents because of the high concentrations of salicylate. One review found that patients who progressed to life-threatening toxicity from oil of wintergreen ingestion almost uniformly experienced emesis within minutes to a few hours of ingestion, followed by signs of CNS toxicity.4

TOPICAL ANESTHETICS
Lidocaine or dibucaine overdose manifests with signs and symptoms of CNS toxicity that progress from agitation, confusion, or ataxia to generalized seizures and coma. Cardiac toxicity, such as heart block or arrhythmia, is infrequently seen with ingestion other than dibucaine and usually occurs only after CNS toxicity has manifested. The onset of symptoms has been reported to occur any time from minutes to hours following exposure, with significantly faster onset if the exposure involves aspiration or the respiratory tract.3 Benzocaine exposures manifest with signs and symptoms that correlate with the percentage of methemoglobin present in the blood. At approximately 15%, patients may exhibit cyanosis unresponsive to supplemental oxygen; weakness, tachycardia, and nausea may occur at approximately 30%. Lethargy and stupor, seizure, coma, and dysrhythmia may occur when methemoglobin levels reach more than 55%; death related to methemoglobinemia, although never reported as a result of benzocaine ingestion, may occur at levels higher than 70%. The onset of symptoms following benzocaine ingestion is usually rapid, occurring within 30 to 60 minutes.

1346
Pulse oximetry and arterial oxygen measurements are not accurate and may be falsely reassuring in these patients. If methemoglobinemia is suspected, methemoglobin must be measured on a cooximeter.

**CAUSTICS**
Contact of caustic substances with mucosa generally causes severe pain, which often limits the quantity of substance ingested. However, even one mouthful of a sufficiently concentrated caustic substance may cause severe injury. Common signs include lip or tongue swelling and erythema or intraoral ulceration. The most common presenting features of a clinically significant exposure include drooling, vomiting, and refusal of oral intake. Substernal chest pain or abdominal pain should raise concern for esophageal or stomach perforation. In severe cases, progressive oropharyngeal edema may lead to drooling and rapid airway compromise.

The severity and rapidity of symptom development are related to the type of agent, concentration, volume, viscosity, duration of contact, and pH. The emergency physician must keep in mind that an absence of oropharyngeal burns does not exclude esophageal injury.17

**HYDROFLUORIC ACID**
Local apparent injury may be minimal because of a paucity of free hydrogen ions, which are responsible for the caustic tissue injuries caused by other acids. A hallmark sign of dermal exposure to hydrofluoric acid is pain out of proportion to physical findings. Evidence of ingestion commonly manifests with gastrointestinal symptoms of nausea, vomiting, and abdominal pain. Respiratory symptoms ranging from dyspnea to acute respiratory distress syndrome can indicate direct inhalational injury, increased secretions caused by fluoride’s effect on acetylcholinesterase, or muscle fatigue.7

CNS manifestations include lethargy, obtundation, weakness, and loss of deep tendon reflexes. Cardiac toxicity, in particular ventricular fibrillation and torsades de pointes, results from hypocalcemia and can develop precipitously. The QTc interval is often prolonged in these patients. The onset of severe systemic symptoms can be delayed, but cardiac toxicity generally occurs within 6 hours.

**CALCIUM CHANNEL BLOCKERS**
Bradycardia and hypotension are the hallmarks of calcium channel blocker overdose. Patients may exhibit sequelae of hypoperfusion and shock, including mental status changes, lactic acidosis, renal or hepatic failure, and intestinal ischemia. Patients may have cardiac arrhythmias including second- and third-degree heart block. Seizures rarely occur in the absence of cardiovascular collapse because these agents, with the exception of nimodipine, do not cross the blood-brain barrier. CNS manifestations out of proportion to the cardiovascular effects should raise the suspicion of coinfections.11

Hyperglycemia is a hallmark of calcium channel blocker toxicity.

Symptom onset usually occurs in 1 to 2 hours, but it may be delayed for up to 24 hours if an extended-release formulation is ingested.

**CLONIDINE AND TOPICAL IMIDAZOLINES**
Clonidine toxicity often resembles opioid intoxication, with symptoms consisting of miosis, bradycardia, hypotension, and, in severe cases, respiratory depression and hypothermia. CNS depression is a common symptom. Unlike with opioid intoxication, patients are often rousable by stimulation, but they may quickly return to a depressed mental state.12,13 Toxicity from topical imidazolines also manifests most commonly with altered mental status and respiratory depression.12 Both topical imidazolines and clonidine may cause tachycardia or bradycardia and hypertension or hypotension.

Both clonidine and the topical imidazolines are rapidly absorbed. Symptoms usually appear in 30 to 90 minutes and may last for 1 to 3 days, depending on the dose ingested.

**DIPHENOXYLATE-ATROPINE (LOMOTIL)**
The classic teaching regarding Lomotil toxicity is that it exhibits a biphasic course: an early, anticholinergic-predominant phase lasting 2 to 3 hours followed by a prolonged, opioid-predominant phase. This notion was challenged by a review in 1991 that suggested that most patients exhibited a prolonged opioid toxidrome, and only 11% presented with a biphasic course.19 In serious intoxications, patients may exhibit CNS excitation, coma, or profound respiratory depression.

The onset of symptoms may occur as early as 2 hours or as late as 24 to 30 hours after ingestion. Respiratory or CNS depression may recur after 12 to 24 hours. The cause is thought to be an accumulation of the long-acting opioid metabolite of diphenoxylate.

**SULFONYLUREAS**
The clinical presentation of sulfonylurea toxicity is that of hypoglycemia: lethargy, confusion, headache, seizures, tachycardia, and diaphoresis. If untreated, hypoglycemia can result in permanent neurologic sequelae or death. The onset of symptoms is usually seen within 8 hours of ingestion, but it can be delayed with ingestion of extended-release formulations. Chlorpropamide, glyburide, and the long-acting form of glipizide tend to have a longer clinical effect. Delayed presentation also seems to correlate with patients in whom a prophylactic dextrose drip is started; this practice may mask emerging hypoglycemia and create a false sense of security.14

**TRICYCLIC ANTIDEPRESSANTS**
The TCA-poisoned pediatric patient presents similarly to the adult patient, with an anticholinergic syndrome of delirium, mydriasis, flushing, tachycardia, dry mucous membranes, or hyperthermia. Hypotension and a widened QRS complex are concerning findings. Pediatric patients exhibit electrocardiographic (ECG) changes similar to those seen adult patients, but no correlation between ECG findings and prognosis has been established.15,18 As with adults, seizure is an ominous sign of potential impending circulatory collapse. When death occurs, it is usually the result of cardiac arrest.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**
In the ideal situation, the differential diagnosis and medical decision making for a given exposure will be guided by knowledge of the ingested agent. Unfortunately, many children ingest toxic agents without direct observation by their caretakers, and the children come to medical care only when
they exhibit signs of intoxication such as altered mental status, respiratory depression, and seizure.

In the patient with an undifferentiated condition who presents with any of these signs of systemic illness, the emergency physician must keep toxic exposure in the differential diagnosis while performing a broad work-up for infectious and metabolic causes of the patient’s illness. A detailed history elicited from the child’s parents and caregivers should include any possible household chemical, prescription, or over-the-counter medications with which the child may have come into contact. This history should include any visitors, such as grandparents, who may have transported their own medications into the home in a purse or suitcase.

The initial evaluation should include a complete blood count, basic chemistry panel with full electrolytes, and bedside glucose determination. An ECG study should be considered to evaluate for arrhythmia, heart block, and QRS widening. In general, serum drug levels are not helpful in guiding initial diagnosis and management because they may not provide clinically useful information other than confirming that a given exposure took place, and results may not be readily available. An exception is the salicylate level, which can be used to guide therapy and management. That said, treatment should not be delayed while awaiting this result when salicylate ingestion is strongly suspected or when the patient is symptomatic. Although acetaminophen is not included on the “One Pill Can Kill” list, an N-acetyl-p-aminophenol (APAP) level is often checked concurrently whenever undifferentiated ingestion is suspected.

During the history or physical examination, the astute physician may pick up a few agent-specific clues that will help guide the diagnosis of a particular toxic exposure in a child with altered mental status. The identification of a cluster of signs and symptoms suggestive of a toxidrome is helpful: anticholinergic symptoms should raise the suspicion of Lomotil or TCA exposure; an opioid toxidrome suggests possible imidazoline or Lomotil exposure. Salicylate overdose and camphor ingestion should be considered in the differential diagnosis of febrile seizure; in salicylate overdose, febrile seizure represents severe salicylate intoxication, whereas in camphor overdose, it reflects parents’ use of camphor to treat symptoms of viral illness. A cyanotic child with symptoms out of proportion to pulse oximetry should raise suspicion of methemoglobinemia and should prompt cooximetry measurement. Significant hypotension should raise concern for TCA, clonidine, calcium channel blocker, or salicylate overdose. Hypoglycemia should raise the suspicion of sulfoniyurea or salicylate exposure; hyperglycemia suggests calcium channel blocker ingestion.

In cases of suspected caustic exposure, pulse oximetry and a chest radiograph may be useful, but radiographic evidence of clinically significant aspiration may not be apparent for 6 hours or more. In a severe caustic ingestion accompanied by chest or abdominal pain, a radiograph should be obtained to evaluate for the presence of free air.

**TREATMENT**

**PREHOSPITAL**

Whenever possible, product or prescription containers should be transported to the hospital with the patient. Given the rapid onset of symptoms seen with many of the agents discussed in this chapter, patients should be transported by ambulance to a hospital facility.

The administration of syrup of ipecac at home is not recommended. A 2004 position paper from the American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) stated that data were insufficient to support or refute the use of syrup of ipecac in the prehospital setting. In highly toxic ingestions by patients in remote locations (i.e., when hospital evaluation will be delayed by hours), ipecac may have a limited role in the prehospital setting if it is administered very early.

Administration of a neutralizing agent, such as vinegar in the case of alkali ingestion, is not recommended because of concerns of inducing emesis or exacerbating injury by causing an exothermic reaction.

**HOSPITAL**

Supportive care is the mainstay of treatment for toxic exposures. The ABCs (airway, breathing, and circulation) are of the utmost importance, and the airway is secured early in patients with compromised respiratory status, mental status depression, or risk of aspiration. Fluid resuscitation should be initiated early and aggressively in patients with hypotension. Seizures, regardless of causative agent, should generally be treated with benzodiazepines as first-line agents and with phenobarbital in refractory cases.

Gastric decontamination in toxic ingestions has historically been a controversial topic and poses unique problems in the pediatric patient. The AACT and EAPCCT’s joint position on the routine use of gastric lavage states that the weight of evidence does not demonstrate a beneficial clinical effect and that the risk of adverse outcomes such as aspiration, laryngospasm, or perforation outweighs the questionable benefits. An additional issue concerning lavage in the pediatric patient is that smaller children may not easily accommodate the 36 to 40 French catheter often needed to remove particulate material effectively.

Single-dose activated charcoal is similarly not recommended for routine use by the AACT and EAPCCT but may be considered in specific cases. Risks associated with charcoal administration include vomiting and aspiration, decreased effectiveness of oral antidotes, and an obscured view of the oropharynx should intubation or endoscopy become necessary. Data from volunteers implied that the reduction of toxin absorption may not be clinically significant if activated charcoal is administered more than 1 hour following ingestion, but a potential benefit after 1 hour cannot be excluded. Charcoal use is contraindicated in a patient without an intact or protected airway. Convincing a toddler to drink a gritty slurry may prove extremely difficult, and the distress caused by forcibly administering this therapy must be weighed against the benefits on a case-by-case basis.

Whole-bowel irrigation is not routinely recommended but should be considered in a patient who has ingested sustained-release or enteric-coated tablets, particularly if the patient presents more than 2 hours following ingestion. This procedure is contraindicated in cases of ileus, bowel obstruction or perforation, hemodynamic instability, or compromised airway.

Agents with specific treatment antidotes or guidelines are discussed next (Table 158.5).
Supplemental Hypoglycemia

ER Ov Atropine, 0.01 mg/kg, or one 0.1 mg pill

Methylene blue is the antidote for benzocaine-induced methemoglobinemia. It works by reducing oxidized hemoglobin back to normal hemoglobin. Methylene blue should be given at a dose of 1 to 2 mg/kg intravenously in patients with serious symptoms or with methemoglobin concentrations greater than 30%. If treatment with methylene blue fails, exchange transfusion or hyperbaric oxygen may be considered. Methylene blue is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency.

Topical Anesthetics

Methylene blue is the antidote for benzocaine-induced methemoglobinemia. It works by reducing oxidized hemoglobin and increasing conversion of methemoglobin back to hemoglobin. Methylene blue should be given at a dose of 1 to 2 mg/kg intravenously in patients with serious symptoms or with methemoglobin concentrations greater than 30%. If treatment with methylene blue fails, exchange transfusion or hyperbaric oxygen may be considered. Methylene blue is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency.

Caustics

Early intubation should be initiated for any patient with any symptom of airway compromise from caustic ingestion. Copious irrigation of the eyes and skin is indicated for dermal and eye exposures. Indications for endoscopy include vomiting, drooling, stridor, and dyspnea. Endoscopy should ideally be performed in the first 12 to 24 hours following exposure.

The administration of corticosteroids in the acute management of caustic ingestion is controversial, and the current evidence does not support use of these agents in preventing stricture formation.25

Hydrofluoric Acid

For significant dermal exposures to hydrofluoric acid, topical use of calcium gel can be effective if it is applied immediately. Local injection of calcium gluconate or arterial calcium gluconate may be needed for significant hand exposures. Patients with severe systemic depletion of electrolytes require aggressive repletion and cardiac monitoring to avoid precipitous decline and progression to lethal arrhythmia.

Calcium Channel Blockers

Calcium channel blocker overdoses in the pediatric patient should be managed aggressively following the same algorithm as for adult ingested, with the use of atropine, calcium, glucagon, vasopressors, or hyperinsulinemia-euglycemic therapy, as warranted (see Chapter 148). Because of the danger of delayed and prolonged presentation, activated charcoal administration or whole-bowel irrigation should be considered in these patients if ingestion of extended-release formulations is suspected.

Clonidine

Naloxone has been shown in some case reports to reverse both cardiovascular and respiratory depression caused by clonidine ingestion, but this is not well studied, and the use of naloxone is recommended only in severe cases or when intubation is imminent.19 Atropine may be used to treat refractory bradycardia, and refractory hypotension may be treated with vasopressors; dopamine is the agent most commonly studied.

Diphenoxylate-Atropine (Lomotil)

Because of the delayed and unpredictable gastric emptying associated with Lomotil, gastric decontamination should be considered in patients with significant Lomotil ingestions. Naloxone has been used in patients exhibiting significant opioid toxicity.

CNS, Central nervous system.
*For a 10-kg child.

Table 158.5 Drugs That Are Highly Toxic in Small Doses
Sulfonylureas
Management of sulfonylurea ingestion is controversial, with widely differing and contradictory recommendations published. Children suspected of ingesting a sulfonylurea should be monitored for a minimum of 8 hours, with blood glucose measurements performed every 1 to 2 hours. Patients should be managed expectantly unless they exhibit signs or symptoms of hypoglycemia. While under observation, patients may be allowed to eat, but they should not be given intravenous glucose infusion.

If a patient develops clinical symptoms or has a blood glucose level lower than 60 mg/dl, then a 1 g/kg bolus of glucose should be given, and the patient should be admitted for inpatient observation. A glucose infusion may be started at the physician’s discretion. Giving exogenous glucose may stimulate an exaggerated endogenous insulin response and lead to rebound hypoglycemia.

For significant and persistent hypoglycemia, octreotide should be administered. Octreotide is a somatostatin analogue that inhibits the secretion of insulin and may obviate the need for exogenous glucose. The dose is 1 to 2 mcg/kg and can be administered subcutaneously or intravenously.

Tricyclic Antidepressants
Pediatric TCA overdoses should be managed aggressively according to the same algorithm that is applied to adults: alkalinization with sodium bicarbonate, benzodiazepines for seizures, and supportive care (see Chapter 147). Given the lethality of a large enough dose and the concern for delayed gastric emptying secondary to anticholinergic effects, activated charcoal should be considered in the first 1 to 2 hours of a known exposure.

FOLLOW-UP AND NEXT STEPS IN CARE

OBSERVATION AND ADMISSION VERSUS DISCHARGE
Regardless of suspected agents, most pediatric patients with toxic exposures or suspected ingestions can be observed for 4 to 6 hours. Patients who remain asymptomatic may be safely discharged home. Exceptions and additional management information relevant to specific substances follow.

Children with suspected salicylate exposure who are found to have a positive blood level require hospital admission with levels rechecked every 2 hours until they are clinically improving, have a decreasing and nontoxic salicylate level, and have an alkalemic blood pH. With respect to calcium channel blocker ingestion, although a 6-hour period of observation is sufficient for ingestions of immediate-release formulations, a 12- to 24-hour observation period is recommended if concern exists about exposure to extended-release formulations.

The observation period for suspected Lomotil ingestion is not well described, especially if significant exposure is a concern. Because symptoms have been shown to be delayed by up to 24 hours, patients with concerning ingestions should be observed for at least this long.

Patients who have ingested sulfonylureas should be monitored for 8 hours because of the possibility of delayed presentation. Patients should be monitored for longer if the ingested medication is a sustained-release formulation.

Hypovolemia is a common crisis in acute care medicine. Loss of volume is often a direct consequence of acute fluid or blood loss, but relative hypovolemia complicates many clinical conditions. Its severity ranges from mild compensated hypovolemia to shock and hypotension that place end-organ perfusion and function at risk. Fluid therapy to optimize cardiac performance and restore fluid and electrolyte balance is a cornerstone of medical support. Timely and appropriate fluid therapy maintains macrocirculatory and microcirculatory support and reduces mortality. In contrast, both underresuscitation and overly aggressive fluid therapy can have an adverse impact on organ function and outcome. Inadequate resuscitation risks leaving a patient in compensated shock. Overly aggressive fluid administration results in volume overload without improving oxygen delivery and is associated with worse clinical outcomes. In addition to sustaining circulating blood volume, intravenous (IV) fluids also correct and maintain normal acid-base and electrolyte balance. A thorough understanding of the appropriate selection, timing, and goals of fluid therapy is vital to optimize patient care.

**PATHOPHYSIOLOGY**

**OXYGEN DELIVERY AND TISSUE PERFUSION**

Oxygen is delivered to cells via the circulation as a function of red blood cell mass and cardiorespiratory function. Oxygen enables continuous production of energy by cells in the form of adenosine triphosphate. Poor oxygenation compromises cell energetics and function and results in the clinical manifestations of organ dysfunction and failure.

Cardiac output is the most important determinant of oxygen delivery, and it has sufficient flexibility to compensate for reduced oxygen-carrying capacity, as well as increased metabolic demands. The physiologic response to a decrease in cardiac output is catecholamine-induced tachycardia and enhanced cardiac contractility, which attempt to maintain oxygen delivery in the face of falling stroke volume. Concomitant vasoconstriction maintains intrathoracic blood volume (preload), whereas arterial vasoconstriction shunts perfusion to vital organs and maintains critical organ perfusion pressure.

Cardiac output and organ perfusion vary dramatically under changing physiologic, pathologic, and pharmacologic stimuli. Organ blood flow is directly proportional to perfusion pressure in most vascular beds. In hypovolemia, protection of arterial (organ perfusion) pressure occurs via peripheral vasoconstriction at the expense of reduced flow to noncritical circulations (e.g., hepatosplanchnic, renal, cutaneous). Consequently, arterial pressure is maintained despite hypovolemia and organ hypoperfusion.

Effective circulating volume (ECV) conceptualizes the portion of intravascular volume contributing to organ perfusion. ECV decreases with hypovolemia but does not necessarily correlate with volume status because organ perfusion is also dependent on cardiac output, vasomotor tone, and circulatory distribution. As an example, ECV may be compromised by limited cardiac output despite optimized intravascular preload status.

Volume depletion describes a state of contracted extracellular fluid with clinical implications of compromised ECV, tissue perfusion, and function. This is distinguished from
dehydration, which implies an intracellular water deficit characterized by plasma hypernatremia and hyperosmolarity.

**WATER**

Water is the most abundant constituent of the body. An adult man weighing 70 kg (154 lb) contains approximately 45 L of water, which accounts for 60% of body mass (Table 159.1). Total body water (TBW) is proportional to lean body mass and affects maintenance fluid requirements. TBW is physiologically compartmentalized into intracellular and extracellular spaces. The extracellular compartment is anatomically and conceptually divided into vascular and interstitial spaces. Water freely crosses cell membranes, and osmotic forces determine the distribution of water within the body. The intracellular and extracellular fluid environments remain isosmolar but physiochemically distinct via tight regulation of dissolved solutes and proteins. Membrane-bound sodium-potassium adenosine triphosphatase pumps compartmentalize sodium and potassium to the extracellular and intracellular spaces, respectively. Active restriction of sodium to the extracellular space is the foundation of isotonic sodium-based resuscitation solutions.

Starling’s law describes the forces governing fluid flux across vascular endothelial membranes. In healthy persons, transcapillary hydrostatic force is nearly opposed by colloid oncotic pressure. Small net loss from the vascular space is ultimately returned to the systemic circulation via lymphatics. Albumin normally accounts for 80% of colloid oncotic pressure, whereas large cellular moieties such as red blood cells and platelets contribute little oncotic pressure effect. Positive hydrostatic pressure, hypoalbuminemia, and pathologic endothelial permeability are common clinical conditions that enhance extravasation of fluid from the vascular compartment. The clinical consequences include large and ongoing volume resuscitation requirements coupled with tissue (e.g., lung, gut, brain) edema, which may compromise function.

**PRESENTING SIGNS AND SYMPTOMS**

**Absolute hypovolemia** occurs as a consequence of loss of water, electrolytes, or blood (or any combination of the three) (Box 159.1). Patients with hypovolemia most often have symptoms related to reduced cardiac output such as fatigue, dyspnea, postural dizziness, and near or true syncope. Tolerance is variable and depends on the acuity and severity of the hypovolemia, associated anemia, individual physiologic reserve, and primary cause. Organ dysfunction is often a heralding sign of hypovolemia and may occur in the absence of global hypoperfusion or frank hemodynamic instability.

**Shock** is defined as a state of inadequate tissue perfusion in which oxygen delivery does not meet metabolic requirements. The term does not reflect perfusion pressure—shock may occur with low, normal, or elevated blood pressure. Unfortunately, clinical signs are unreliable indicators of oxygen delivery and blood volume.5,6

**Compensated shock** refers to inadequate perfusion in the setting of normal blood pressure. The majority of critically ill patients are in compensated shock. The difficulty in identifying these patients prompted the terms occult and cryptic shock to describe normotensive patients with alternative evidence of cardiovascular insufficiency. Hyperlactatemia (<3 mmol/L) is an important marker to aid in identification of these high-risk patients.7 Left unresuscitated, these patients often progress to frank hypotension.
Brief episodes of hypotension are important markers of hypoperfusion and herald progressive hemodynamic deterioration. These self-limited episodes of transient hypotension represent progressive exhaustion of cardiovascular compensation and are the first sign of uncompensated shock. Uncompensated shock is characterized by hypotension that occurs when physiologic attempts to maintain normal perfusion pressure are overwhelmed or exhausted. Sustained hypotension signifies a late stage of shock.

Volume status and perfusion should be evaluated during every emergency department (ED) examination (Box 159.2). Delayed capillary refill, dry axillae and mucous membranes, abnormal skin turgor, sunken eyes, and a depressed fontanelle are classic but imperfect hallmarks of hypovolemia.9,10 Peripher-eral cyanosis, cool extremities, and cutaneous mottling (cutis marmorata) characterize classic hypodynamic shock but are not a primary indication of hypovolemia. In contrast, early hyperdynamic septic shock may be manifested as peripheral vasodilation with warm extremities and brisk capillary refill.

Generalized tissue edema reflects total body sodium and fluid excess but does not quantify intravascular status and may be accompanied by hypovolemia, especially in acute illness. Acute weight change implies loss of fluid rather than lean body mass and is helpful in patients with a reliable comparison weight.

**PRIORITY ACTIONS**

**Prioritized End Points of Fluid Resuscitation**

- Adequate intravenous access
- Mean arterial pressure > 65 mm Hg
- Systemic perfusion
  - Central venous oxygen saturation (Scvo₂) > 70%
  - Serum lactate clearance (>5%/hr) and normalization (<2 mmol/L)
- Regional perfusion
  - Urine output (>0.5 mL/kg/hr)
  - Normalized peripheral perfusion

**TREATMENT**

Circulatory failure is the final common pathway of many diseases. Inadequate circulating volume is the most common and immediately reversible factor in patients with acute circulatory insufficiency. Accordingly, fluid therapy is the initial management of undifferentiated shock. Pathologic vasodilation compounds the fluid deficit in common conditions such as sepsis, anaphylaxis, adrenal failure, neurogenic shock, and toxin-induced shock. Acute cardiac decompensation and pulmonary embolism are two exceptional situations in which limited volume resuscitation takes secondary priority to catecholamine and mechanical support.

Early recognition of hypovolemia and shock must be coupled with aggressive resuscitation to have an effect on patients. Timely resuscitation is important because the window to reverse critical organ hypoperfusion and affect clinical outcome is measured in hours and often transpires in the ED.11 Equivalent but delayed resuscitation yields greater morbidity and mortality.12,13 The immediate goal of fluid resuscitation is intravascular expansion to optimize stroke volume and oxygen delivery.

**FLUID RESUSCITATION**

**Resuscitation Targets (End Points)**

The target end point of resuscitation guides the dose and selection of interventions, including fluid therapy. In high-risk patients, fluid selection appears to be less important than volume dosage titrated to an appropriate therapeutic end point.1,16 Rapid restoration of systemic pressure (mean arterial pressure > 65 mm Hg) is a first priority to support vital organ autoregulated blood flow. However, stabilization of blood pressure does not guarantee adequate organ perfusion—resuscitation aimed primarily at normotension risks leaving the patient in persistent compensated shock.17 Unfortunately, there is no single best resuscitation end point for all clinical circumstances. An approach seeking to normalize a combination of both global and regional perfusion markers is most prudent (Box 159.3).

**Empiric Fluid Challenge**

Empiric volume challenges remain the standard means of early fluid resuscitation. Volume expansion is achieved by infusing serial aliquots of isotonic fluid under direct observation. This strategy is appropriate for acute undifferentiated shock or for obvious or suspected hypovolemia. Crystalloid (10 to 20 mL/kg) or colloid (4 to 7 mL/kg) should be infused rapidly over a period of 15 minutes with serial boluses titrated to the clinical end point objective while monitoring for adverse effects. A positive clinical response to volume loading confirms volume responsiveness but does not predict further response to therapy. Failure to recognize patients not
responding to fluid may contribute to overly aggressive volume therapy and delay alternative care measures.

Total volume requirements are difficult to predict at the onset of resuscitation and are often underestimated. Classic hypovolemia, as occurs with acute hemorrhage or fluid loss, may stabilize rapidly with appropriate volume expansion. The 3:1 rule of hemorrhage resuscitation suggests that 3 volumetric units of crystalloid are required to replete an extracellular fluid deficit of 1 unit of blood loss. However, experimental models have confirmed that with severe hemorrhage, volume requirements exceed the 3:1 suggestion. Pathologic vasodilation and capillary leak contribute to the need for ongoing volume replacement. Exaggerated transcapillary fluid shifts are common with early burns, peritonitis, and pancreatitis. Crystallloid requirements average greater than 60 mL/kg in the first hours of septic shock but may be as high as 200 mL/kg to normalize perfusion.18,19

**Predicting Volume Responsiveness**

The utility of fluid administration to improve stroke volume depends on a number of variables, including venous tone and ventricular function. Critically ill patients may manifest continued hypoperfusion despite initial empiric volume resuscitation. As an example, only half of hypotensive patients with sepsis are stabilized with volume resuscitation alone.19 In the absence of overt clinical hypovolemia or ongoing fluid loss, volume responsiveness should not be assumed. Continued fluid therapy does not have any impact on macrocirculatory flow in up to 50% of critically ill patients.20

Volume or preload responsiveness refers to the ability to augment stroke volume with fluid administration. In contrast to an empiric volume challenge, volume responsiveness is gauged before fluid administration, and the resulting information is used to guide whether fluid administration is a solution to reverse clinical hypoperfusion. Fluid loading in volume-unresponsive patients is optimally avoided because it delays appropriate therapy and contributes to fluid excess that contributes to organ dysfunction, including hypoxic respiratory failure and abdominal compartment syndrome. A more rational approach for patients who remain hypoperfused after initial empiric management incorporates selection and titration of subsequent therapy under the guidance of objective cardiovascular monitoring.

A target central venous pressure (CVP) of 8 to 12 mm Hg is recommended to maximize preload before instituting pressor and inotropic support.21 Unfortunately, there is no consistent threshold CVP to reliably estimate response to fluid administration.22 Values that are considered low, normal, or high can be found in patients who respond positively to fluid.20

Dynamic hemodynamic indices are more dependable signs of volume responsiveness. Respiratory variation in stroke volume during positive pressure mechanical ventilation is among the most useful signs of fluid responsiveness.20 Respiratory collapse of the inferior vena cava (IVC) is another helpful indicator. Minimal IVC variation is associated with supranormal CVP and a low probability of fluid responsiveness. Inspiratory IVC collapse greater than 50% indicates a high probability of augmenting stroke volume with fluid therapy.

**FLUID SELECTION**

Early resuscitation and ongoing replacement of fluid deficits may be performed with a variety of fluids. Because each possesses specific benefits and potential disadvantages in given clinical scenarios, an understanding of fluid composition is important. Isotonic solutions are effective volume expanders (Table 159.2). Electrolyte disorders (including hypernatremia and hyponatremia) take secondary priority to isotonic volume loading in hypoperfused patients. Hypotonic solutions are ineffective and inappropriate volume expanders.

**Crystalloids**

Isotonic sodium-based crystalloids are distributed to the extracellular compartment, which includes the vascular space. Partitioning within the extracellular fluid leaves 25% of the infused volume within the circulation. Normal saline and lactated Ringer (LR) solution are two isotonic resuscitation solutions in common use. LR solution, also known as Hartmann solution, was developed as a more physiologic alkalinizing replacement solution; bicarbonate is generated by lactate metabolism via the Cori cycle.

The clinical superiority of any single crystalloid remains unproved, and selection of fluid should be based on the source of the hypovolemia, associated electrolyte derangements, and volume requirements. Normal saline provides a supraphysiologic chloride load that induces metabolic acidosis when administered in large volumes. This is advantageous in correcting the volume and electrolyte disturbances (hypochloremic metabolic acidosis) associated with loss of gastric secretions (e.g., profuse vomiting, gastric outlet obstruction, nasogastric suctioning). LR solution provides a more physiologic electrolyte balance and is often preferred for large-volume resuscitation. LR is recommended for trauma resuscitation but is incompatible with blood. Isotonic bicarbonate (i.e., three ampules of sodium bicarbonate in 1 L of sterile water) is an alternative resuscitation fluid for patients with coexisting metabolic acidosis.

**Colloids**

Colloid solutions are composed of electrolyte preparations reinforced with macromolecules designed to preserve colloid oncotic pressure. Vascular retention of colloid makes these formulations more efficient volume expanders with a longer duration of action than is the case with crystalloids. Crystalloid solutions require two to four times more volume for equivalent resuscitation. Dilutional hypoalbuminemia, transcapillary fluid shift, and interstitial and pulmonary edema may therefore be limited with colloid use. When dosed to the same end points, colloids and crystalloids are equally effective. Randomized clinical trials have failed to prove clinical superiority of one fluid class, with comparable rates of mortality and lung dysfunction.23,24 Traumatic brain injury remains one important exception in which isotonic albumin is associated with a higher risk for adverse outcomes when compared with equivalent crystalloid.25,26 Crystalloid solutions remain the standard ED choice for resuscitation and confer a significant cost advantage over colloid solutions.

Human albumin and hydroxyethyl starch (HES) are the colloids primarily used in clinical practice in the United States. Human albumin solutions are heat-sterilized.
derivatives of donor plasma. Isotonic 5% albumin is recommended for resuscitation of patients with severe hypoalbuminemia and end-stage liver disease, but there is little outcome evidence to support this position. HES, a semisynthetic polymerized amylpectin compound, has supplanted dextran and gelatin-based colloids. A 6% solution provides volume expansion equivalent to that of 5% albumin. The renal dysfunction and coagulopathy that complicated early-generation synthetic colloids do not appear to be clinically significant with new-generation HES solutions.

**Hypertonic Solutions**

**Hypertoncotic Albumin** Infusions of hyperoncotic albumin (20% to 25%) result in vascular expansion greater than two times the volume administered. Besides the obvious benefits of small-volume resuscitation, improved portability, and more rapid hemodynamic stabilization, hyperoncotic albumin has additional advantages. Synergistic interaction with administered drugs and primary antioxidant effects are explanations hypothesized for the improved morbidity linked to hyperoncotic albumin administered to patients with complicated hypoalbuminemic states. End-stage liver disease is one important example in which hyperoncotic albumin attenuates renal dysfunction and death in patients with spontaneous bacterial peritonitis or those undergoing large-volume paracentesis.

**Hypertonic Saline** Hypertonic sodium solutions rapidly expand intravascular volume by mobilizing water from the interstitial and intracellular spaces. A small infusion expands plasma several times the volume infused. Used alone, the hemodynamic impact of hypertonic crystalloid is transient. Hypertonic crystalloid is often used in combination with hyperoncotic colloid (6% dextran or 10% HES) to sustain vascular expansion. Animal resuscitation models have demonstrated additional benefits, including enhanced cardiac output, improved microcirculatory flow, and attenuated inflammatory response. Hypertonic saline is safe, but data are insufficient to conclude that it is better than isotonic crystalloid for the resuscitation of patients with burns, trauma, or sepsis. Severely traumatized patients with associated traumatic brain injury remain an exceptional use for hypertonic saline, but outcome evidence is mixed.

**SPECIAL TREATMENT CONSIDERATIONS**

**Minimal-Volume Resuscitation of Hemorrhagic Shock**

Traditional resuscitation of hemorrhagic shock prioritized rapid restoration of circulating blood volume with crystalloid and blood products. Strategic limited-volume resuscitation for uncontrolled hemorrhage dates back to the early 1900s and reemerged in the 1980s.

The rationale is that the increased intravascular pressure and hemodilution resulting from aggressive fluid resuscitation compounds the blood loss by precipitating rebleeding from hemostatic sites. Animal models of uncontrolled hemorrhage reveal that aggressive fluid administration reduces oxygen delivery and results in higher mortality. The widely recognized Houston experience showed a mortality benefit in penetrating trauma victims, but the results have yet to be matched.

by other investigators. In this strategy, hypotensive patients with a source of uncontrolled life-threatening hemorrhage receive IV fluids titrated to sustain critical organ flow until definitive surgical control is achieved (see Box 159.3). Conventional resuscitation ensues once surgical hemostasis is achieved.

The degree and duration of permissive hypotension remain to be clarified, although current recommendations target a systolic blood pressure of 70 mm Hg. Patients with concomitant traumatic brain injury are not candidates for this strategy.

BURN RESUSCITATION
Patients with partial-thickness and full-thickness burns exhibit marked fluid shifts related to denuded skin, injured tissue, and the systemic inflammatory response. Early anticipation of these large fluid requirements prevents underresuscitation. The Parkland formula remains the most commonly used guide for acute burn resuscitation. Formula calculations are based on the time of injury rather than the time until medical attention and incorporate prehospital fluid administration. All burn formulas provide only estimates of fluid requirements. The requirements must be modified and individualized based on patient response because volume needs may substantially exceed formula approximation. LR solution is the resuscitation crystalloid preparation of choice for acute burn management. In addition to burn formula replacement, maintenance fluid requirements should be allocated. Urine output greater than 1 mL/kg/hr is a traditional end point of acute burn resuscitation and may be augmented by the perfusion end points discussed earlier.

Oral Rehydration Therapy
Oral rehydration therapy is a valuable tool for maintenance and correction of mild to moderate dehydration secondary to gastroenteritis in children and adults. It remains underused in the United States despite worldwide success, guideline support, and evidence from controlled trials. When used as per published guidelines, oral rehydration therapy is comparable with IV therapy, but with reduced hospitalization and improved safety and expense. Small aliquots of fluid (as low as 5 mL, depending on patient size and tolerance) are administered by bottle, spoon, syringe, or nasogastric tube at regular 2- to 5-minute intervals to meet deficit and maintenance goals. After patient and family education, appropriate fluid selection is the most important factor in successful oral rehydration therapy.

Many common household fluids, including fruit juice, sport drinks, carbonated beverages, and soups, contain poorly tolerated concentrations of sugar and salt. Commercial (e.g., Rehydration, Pedialyte) and reconstituted liquids (oral rehydration salts or home recipe) are balanced, low-carbohydrate enteral solutions. One recipe for an oral rehydration solution containing home ingredients consists of 1 L of water, 8 teaspoons of sugar, and 1 teaspoon of salt.

Maintenance Fluid Therapy
The goal of maintenance fluid therapy is normal body fluid composition and volume. Fluid orders anticipate daily fluid requirements, ongoing losses, and coexisting electrolyte abnormalities. Though often ordered concurrently, the estimated physiologic fluid (true maintenance) should be consciously distinguished from therapy aimed to replace an existing fluid deficit.

Routine water and electrolyte maintenance is based on normal energy expenditure, sensible loss from urine and stool, and insensible loss from the respiratory tract and skin. Calculations assume euvolemia and are adjusted for body mass. The greater per-kilogram fluid requirements in children are proportionate to their TBW and metabolism (Table 159.3).

All maintenance prescriptions should be individualized—energy expenditure, fluid losses, and electrolyte status vary with disease and dictate the rate and electrolyte modifications. For example, exfoliative skin disease, increased work of breathing, and fever enhance insensible loss. Measurable nasogastric, fistula, ostomy, and urinary drainage can be estimated and replaced per drained volume. Limitation of fluid and potassium is an important disease-specific modification for patients with renal insufficiency.

Hypotonic solutions (e.g., 0.45% and 0.2% sodium chloride) with or without dextrose and potassium are popular fixed-combination maintenance solutions. Hospitalized patients often suffer impaired free water excretion because of nonosmotic release of antidiuretic hormone, which makes them vulnerable to hyponatremia. The serum sodium concentration provides a simple and accurate marker of hydration status. Isotonic maintenance solutions should be considered in all patients (including children), especially those with a serum sodium concentration of less than 138 mEq/L. Glucose infusions are best formulated by adding dextrose to an electrolyte solution (e.g., LR solution, 0.45% or 0.9% normal saline) rather than using 5% dextrose in water, which behaves as electrolyte-free water on sugar metabolism.

*Note that the following two formulas calculate disparate rates. The difference between these calculated rates is clinically insignificant. Sodium and chloride—2 to 3 mEq per 100 mL water; potassium—1 to 2 mEq per 100 mL water. D,NS with 20 mEq KCl is a common maintenance solution for most euvolemic pediatric patients and provides 20% of the daily calories at a routine maintenance rate. Comorbid conditions or electrolyte abnormalities may require modification.

Acid-Base Disorders
Matthew T. Robinson and Alan C. Heffner

Chemical Buffering
Extracellular buffers, including plasma proteins, phosphates, and bicarbonate, are the earliest defense against acidosis. The most prominent extracellular buffer is bicarbonate, which is highly abundant and acts as a dynamic buffer by independently regulating \( \text{PCO}_2 \) through changes in alveolar ventilation. This feature increases buffering capacity by more than 10-fold. Buffering also occurs within the intracellular compartment but is delayed as \( \text{H}^+ \) equilibrates over a period of hours. Intracellular buffers, including bone, inorganic phosphates, proteins, and hemoglobin, are eventually responsible for more than 50% of the overall chemical buffering capacity.

Alterations in Alveolar Ventilation
Alterations in alveolar ventilation provide compensation for acute acid-base disturbances. According to the Henderson-Hasselbalch equation, serum pH can be determined as follows:

\[
\text{pH} = 6.1 + \log[\text{HCO}_3^-]/0.03 (\text{PCO}_2)
\]

Stimulation of peripheral chemoreceptors triggers changes in ventilation within minutes. By altering \( \text{PCO}_2 \) through variations in minute ventilation, the \( \text{HCO}_3^-/\text{PCO}_2 \) ratio remains relatively constant, and alterations in pH are thereby mitigated. The effectiveness of the ventilatory response is acutely limited by differences in the solubility of \( \text{CO}_2 \) and \( \text{H}^+ \) within the central nervous system (CNS). The hyperventilation induced by systemic acidosis is incomplete as a result of local alkalosis sensed by the central chemoreceptors as \( \text{CO}_2 \) diffuses more rapidly across the blood-brain barrier.

Alterations in Renal Hydrogen Ion Excretion
Because of the inability of \( \text{HCO}_3^- \) to effectively buffer \( \text{H}_2\text{CO}_3 \) produced through acute \( \text{CO}_2 \) retention as described, renal compensation is centrally important in the response to primary respiratory disorders. Renal compensatory mechanisms include enhanced proton excretion and increased \( \text{HCO}_3^- \) resorption. Renal compensation for acute acid-base disorders begins immediately; however, the full effect is not appreciated for 5 or 6 days.

Nomenclature
The normal range of serum pH is 7.38 to 7.42. Acidemia is defined by serum pH below 7.38. Likewise, alkalemia is defined by serum pH above 7.42. These terms describe the absolute directional change of measured pH but say nothing about the processes that alter pH from normal. The processes that alter pH are termed acidosis and alkalosis.

KEY POINTS
- Normal pH or serum bicarbonate values can mask an important, underlying acidosis in the setting of a mixed disorder.
- An elevated anion gap is a sign of metabolic acidosis and should be calculated on each chemistry sample.
- Arterial and venous blood gas sampling is a useful emergency department test because of the strong association between arterial and venous \( \text{HCO}_3^- \) and pH.
- Correlation between venous \( \text{PCO}_2 \) and arterial \( \text{PCO}_2 \) is lacking, although venous \( \text{PCO}_2 \) levels may be used as a screening tool for hypercapnia.
- Admission lactate level and standard base excess are markers of illness severity that correlate with patient morbidity and mortality in the hospital.
- The urine ketone dipstick test is highly sensitive for serum ketosis.
- Venous and arterial lactate samples are equivalent.
- Indiscriminate use of sodium bicarbonate for the treatment of undifferentiated metabolic acidosis should be avoided.

PATHOPHYSIOLOGY

REGULATION OF ACID-BASE BALANCE
The normal hydrogen ion (\( \text{H}^+ \)) concentration in serum is approximately 40 nanoequivalents per liter. This is approximately 1/1,000,000 the concentration of the other major serum ions, but the small size and high charge density of protons make them highly reactive and capable of inducing conformational and functional changes in body proteins. Rigid control of the free \( \text{H}^+ \) concentration is therefore essential to life.

Daily metabolism produces an acid load of 150 mmol of nonvolatile (fixed) acid and 12,000 mmol of volatile acid (\( \text{CO}_2 \)). Physiologic, pathologic, and dysregulated endogenous production, as well as externally administered product, can all increase the systemic acid load.

Maintenance of systemic homeostasis in the setting of acid-base changes occurs via three main mechanisms:

1. Chemical buffering
2. Alterations in alveolar ventilation
3. Alterations in renal \( \text{H}^+ \) excretion
Acid-base disorders are often complex—pH may be normal in the setting of an obvious acid-base disorder because of the presence of a second or even a third coexisting acid-base process. For example, patients with a mixed disorder may have a normal or alkaline pH during ketoacidosis if a concomitant alkalosis (metabolic or respiratory) is also present. It is therefore important to note that a normal pH does not exclude an important acid-base disorder.

**DIAGNOSTIC INTERPRETATION**

Primary acid-base processes are divided into respiratory or metabolic disorders by examining $P_{\text{CO}_2}$ and serum bicarbonate. Primary elevations in $P_{\text{CO}_2}$ signify respiratory acidosis, whereas decreased serum bicarbonate identifies metabolic acidosis. Diagnostic assessment of acid-base disorders requires accurate measurement of these plasma variables, in addition to calculated values, to unmask mixed disorders. Coupling the clinical history and physical assessment with these values reveals important clues about the causative illness.

Serum testing includes direct evaluation of pH, $P_{\text{CO}_2}$, and $\text{HCO}_3^-$ through arterial and venous blood sampling; calculation of the anion gap from serum chemistries; and additional measures (e.g., the standard base excess) in an attempt to quantify the metabolic component of acid-base disorders (see the “Facts and Formulas” box for basic formulas used in this chapter).

**FACTS AND FORMULAS**

\[
\text{pH} = 6.1 + \log[(\text{HCO}_3^-)/0.03 \times P_{\text{CO}_2}]
\]

Anion gap = Unmeasured anions - Unmeasured cations = $\text{Na}^+ - [\text{Cl}^- + \text{HCO}_3^-]$  

Delta gap = \Delta \text{Anion gap} - \Delta \text{HCO}_3^- = [\text{Calculated anion gap} - 10] - [24 - \text{Measured serum HCO}_3^-]  

Calculated Sosm (mOsm/kg) = 2 (\text{Na}^+) + \text{BUN}/2.8 + \text{Glucose}/18 + \text{Ethanol}/4.8  

Osmolal gap = Measured Sosm - Calculated Sosm  

**Correction Formulas**

Corrected anion gap = Anion gap + 2.5 (Normal albumin - Measured albumin)  

**Compensation Formulas**

Metabolic acidosis: $P_{\text{CO}_2} = 1.5 \ (\text{HCO}_3^-) + 8$  

Metabolic alkalosis: Increase in $P_{\text{CO}_2} = 0.6 \times \text{Increase in} \ \text{HCO}_3^-$  

Respiratory acidosis  

- Acute: $[\text{HCO}_3^-]$ increases by 1 mEq/L for each 10-mm Hg increase in $P_{\text{CO}_2}$  
- Chronic: $[\text{HCO}_3^-]$ increases by 4 mEq/L for each 10-mm Hg increase in $P_{\text{CO}_2}$  

Respiratory alkalosis  

- Acute: $[\text{HCO}_3^-]$ decreases by 2 mEq/L for each 10-mm Hg decrease in $P_{\text{CO}_2}$  
- Chronic: $[\text{HCO}_3^-]$ decreases by 5 mEq/L for each 10-mm Hg decrease in $P_{\text{CO}_2}$

**Lactate**

Lactic acid is generated through the reduction of pyruvate with the reduced form of nicotinamide adenine dinucleotide (NADH) as follows:

\[
\text{Pyruvate} + \text{NADH} \rightleftharpoons \text{Lactate} + \text{NAD}^+
\]

Lactate is produced by skeletal muscle, brain, intestines, and kidneys, with normal blood lactate levels maintained below 2 mmol/L and the threshold for lactic acidosis defined by a serum level higher than 4 mmol/L.

Arterial lactate sampling is considered the most reliable measure for detecting hyperlactatemia; however, venous and capillary sampling is also used. Central venous sampling is highly correlated with arterial lactate measurements. Peripher al venous samples are sufficient to screen for hyperlactatemia but retain poor specificity (57%) when compared with arterial samples. Elevations in venous lactate should be confirmed with arterial sampling.

**ANION GAP**

Within serum, the requirement for electroneutrality dictates that the net serum cation charge equal the net total anion charge. The calculated difference in commonly measured serum ions is termed the anion gap (AG). It is important to note that the AG represents anions that are present but unmeasured (at least historically) and that an AG is present during health. Fortunately, the difference between unmeasured anions
and unmeasured cations may change (increased or decreased AG) and therefore provide a clue to disease states (Box 160.1).

The greatest utility of the AG is identification and discrimination of metabolic acidosis. The potential for a mixed acid-base disturbance to mask acidosis by normalizing pH and serum bicarbonate highlights the importance of calculating the AG on every chemistry sample. An increased AG almost always signifies a process causing a “wide-gap” metabolic acidosis. Furthermore, calculation of the AG assists in discriminating the cause of undifferentiated metabolic acidosis. Furthermore, calculation of the AG assists in discriminating the cause of undifferentiated metabolic acidosis (e.g., AG versus non-AG processes carry different differential diagnoses).

When acids are added to the system, bicarbonate is replaced by the acid anion (X) as follows:

\[
HX + \text{NaHCO}_3 \rightarrow \text{NaX} + \text{H}_2\text{O} + \text{CO}_2
\]

Titration and replacement of bicarbonate by unmeasured organic acid produce a relative equimolar elevation in the AG.

In contrast, bicarbonate loss (or addition of protons) can occur in the absence of an endogenous or exogenous anion contribution.

\[
\text{HCl} + \text{NaHCO}_3 \rightarrow \text{NaCl} + \text{H}_2\text{CO}_3 \rightarrow \text{CO}_2 + \text{H}_2\text{O}
\]

Hyperchloremia maintains electroneutrality without altering the AG. Gastrointestinal and renal losses are the most common causes of non-AG metabolic acidosis (Box 160.2).

The historical range for the AG was 12 ± 4 (8 to 16 mEq/L). With the adoption of ion-specific electrodes, chloride is measured at a higher concentration such that the currently accepted range of AG is 7 ± 3 (4 to 10 mEq/L). More importantly, the AG must be corrected for individual patients. Albumin accounts for 80% of the AG in health. Consequently, large and important deviations may occur if serum albumin is assumed to be normal. AG is thus commonly corrected for serum albumin to improve sensitivity of the AG as a screening tool. The correction factor is calculated as follows:

\[
\text{Corrected AG} = \text{Calculated AG} + 2.5 \times \left(\frac{\text{Normal Measured albumin} - \text{Measured albumin}}{\text{g/dL}}\right)
\]

**Delta-Delta Calculation**

The AG is also useful for investigating the presence of mixed metabolic disturbances. In simple AG acidosis, bicarbonate is presumably titrated in a one-to-one fashion by organic acid such that the following relationship is noted:

\[
\text{Increase in AG} = \text{Decrease in HCO}_3^-
\]

The difference between the change in the AG and the change in serum bicarbonate is called the delta gap, or delta-delta calculation. Deviations from this stoichiometric relationship indicate a mixed metabolic disturbance. When the change (delta) in the AG is greater than the change in bicarbonate, a preexisting or concomitant metabolic alkalosis is present. Alternatively, a change in AG less than the change in bicarbonate identifies a coexisting non-AG acidosis. A delta gap higher than 6 is generally considered significant.

**Serum Osmolar Gap**

Osmolarity is defined as the number of particles within a volume of fluid (mmol/L), and osmolality is defined as the number of particles in a mass of fluid (mmol/kg). The terms are used interchangeably because the density of water is 1 kg/L. The size of the particle contributing to serum osmolality (Sosm) is unimportant; that is, small ions contribute equally with large proteins.

Sosm is elevated in the presence of osmotically active particles such as alcohols, glycols, and sugars. The difference in measured and calculated Sosm is termed the osmolar gap. An elevated osmolar gap confirms the presence of unmeasured osmotically active particles, which may be helpful.
when investigating the cause of unexplained AG acidosis. Osmolar gaps greater than 10 mOsm/kg are considered abnormal and may reflect the presence of a toxic alcohol as the source of the acidosis. However, delayed evaluation after the ingestion of toxic alcohol will show little to no elevation in the osmolar gap as a result of metabolism of the offending alcohol. Likewise, normal osmolar gap values are imprecisely defined, with ranges of −13 to +14.0 mOsm/kg noted in healthy patients.10,21 This wide variation in the normal range may lead to a normal osmolar gap in the presence of a significant ingestion.

**Evaluation of Mixed Acid-Base Disorders**

By applying the formulas for AG, delta gap, and expected physiologic compensation, a stepwise approach to the evaluation of simple and mixed acid-base problems can be developed.12 This process is summarized in Box 160.3.

Additionally the clinical history is centrally important for proper interpretation of acid-base disorders (Box 160.4).

### SPECIFIC ACID-BASE DISORDERS

#### RESPIRATORY ACIDOSIS

Normal ventilatory control is regulated through central receptors that respond to elevated PCO₂ and through peripheral chemoreceptors in the carotid bodies that respond to hypoxia. Because the ventilatory response to hypercapnia is much stronger than to hypoxemia, only minor elevations in PCO₂ are required to increase minute ventilation. As a result of this vigorous response and the ability to significantly increase minute ventilation, respiratory acidosis almost always develops as a consequence of impaired alveolar ventilation and not from increased production of CO₂.

Elevated PCO₂ causes a decrease in arterial pH and a variable, acute increase in plasma HCO₃⁻ as a result of shifts in equilibrium reactions and a similar, but chronic increase as a result of renal compensation through enhanced H⁺ excretion and HCO₃⁻ retention. CO₂ functions as a volatile acid:

\[
H^+ + HCO_3^- \rightarrow H_2CO_3 + H_2O + CO_2
\]

Under normal conditions, this acid load is immediately buffered by intracellular and extracellular nonbicarbonate buffers. The acute rise in PCO₂ elicits a similar elevation in HCO₃⁻ through a highly predictable relationship:

\[
[HCO_3^-] \text{ increases by } 1 \text{ mEq/L for each } 10\text{--mm Hg increase in PCO}_2
\]

In chronic respiratory acidosis, elevations in PCO₂ are partially protective, with larger amounts of CO₂ able to be excreted at lower minute ventilation. The system also adapts to chronically elevated CO₂ by enhancing renal H⁺ excretion and HCO₃⁻ retention, thereby attenuating the ventilatory response to hypercapnia. The result of chronic respiratory acidosis is that the ventilatory drive becomes dependent on a hypoxic stimulus.

The renal compensatory response in patients with chronic respiratory acidosis requires 3 to 5 days to develop and may be predicted by the following equation:

\[
[HCO_3^-] \text{ increases by } 4 \text{ mEq/L for each } 10\text{--mm Hg increase in PCO}_2
\]

#### RESPIRATORY ALKALOSIS

Respiratory alkalosis is produced through alveolar hyperventilation and results in a decrease in arterial PCO₂ and an increase in arterial pH. Plasma HCO₃⁻ is variably decreased, acutely because of shifts in equilibrium and later because of renal HCO₃⁻ wasting. The decreased PCO₂ causes a decreased volatile acid load with secondary release of H⁺ from nonbicarbonate buffers (Buf) as follows:

BOX 160.4 Acid-Base Interpretation Based on Clinical History

**Case 1**
A 65-year-old man with a history of chronic obstructive pulmonary disease has had fever, increased shortness of breath, cough, and sputum production. The following arterial blood gas and serum HCO₃⁻ values are obtained:
- pH = 7.27
- PCO₂ = 65 mm Hg
- HCO₃⁻ = 29 mEq/L
- PO₂ = 70 mm Hg

Review shows decreased pH and elevated PCO₂, indicative of respiratory acidosis. The chronicity of the acidosis can be evaluated by calculating the expected metabolic compensation:
- Acute: [HCO₃⁻] increases by 1 mEq/L for each 10-mm Hg in PCO₂
- Expected HCO₃⁻ = 24 + 2.5 = 26.5
- Chronic: [HCO₃⁻] increases by 4 mEq/L for each 10-mm Hg in PCO₂
- Expected HCO₃⁻ = 24 + 10 = 34

Comparing these values with the measured HCO₃⁻ reveals that HCO₃⁻ falls between the two calculated levels. Based on the history, the clinical diagnosis is acute on chronic respiratory acidosis.

**Case 2**
A 65-year-old man with a history of chronic obstructive pulmonary disease has had diarrhea for 1 week and his baseline PCO₂ is 65 mm Hg.

Based on his history, the patient’s HCO₃⁻ is lower than predicted, which represents acute metabolic acidosis in the presence of chronic respiratory acidosis.

**Case 3**
A 65-year-old man being treated long-term with diuretic therapy has an acute exacerbation of asthma.

His history indicates acute respiratory acidosis with an expected PCO₂ of 26.5 mm Hg. The elevated serum HCO₃⁻ indicates acute respiratory acidosis with concomitant metabolic alkalosis.

The renal compensatory response in chronic respiratory acidosis requires 3 to 5 days to develop and may be predicted by the following equation:
- [HCO₃⁻] increases by 4 mEq/L for each 10-mm Hg increase in PCO₂

HCO₃⁻ + HBuf → H₂CO₃ + Buf → CO₂ + H₂O

The expected [HCO₃⁻] can be calculated from the following equation:

[|HCO₃⁻|] decreases by 2 mEq/L for each 10-mm Hg decrease in PCO₂

In chronic respiratory alkalosis, renal adaptive mechanisms result in diminished H⁺ secretion and enhanced HCO₃⁻ excretion. This combined response begins within hours and is completed within 2 to 3 days. The expected response may be calculated as follows:

BOX 160.5 Diabetic Patient with Mixed Acid-Base Disorder

A 26-year-old woman with a history of diabetes mellitus is vomiting and has had generalized malaise for the past 3 days.

Laboratory evaluation shows the following:
- Na⁺ = 134; K⁺ = 4.6; Cl⁻ = 94; HCO₃⁻ = 20 mEq/L; pH = 7.38; PCO₂ = 35 mm Hg

Step 1: Arterial blood gas analysis shows that the patient is minimally acidemic

Step 2: Serum bicarbonate is less than 25 mEq/L, indicative of metabolic acidosis

Step 3: The anion gap is elevated: 134 – 94 – 20 = 20

Step 4: Respiratory compensation is appropriate: 1.5 [HCO₃⁻] + 8 = [1.5 × 20] + 8 = 38 mm Hg

Step 5: Calculation of the delta gap reveals that the change in HCO₃⁻ (24 – 20 = 4 units) is significantly less than the change in anion gap (20 – 10 = 10 units). This indicates the presence of a concomitant metabolic alkalosis that is masking the significant anion gap acidosis. These findings are explained by vomiting-induced alkalosis in a patient with diabetic ketoacidosis

[HCO₃⁻] decreases by 5 mEq/L for each 10-mm Hg decrease in PCO₂

Ventilation is primarily controlled through peripheral, central, and pulmonary mechanical receptors. Peripheral chemoreceptors respond to changes in PCO₂ and O₂, so it is not surprising that many cases of hyperventilation stem from hypoxemia.

**METABOLIC ACIDOSIS**

Metabolic acidosis is induced by the addition of H⁺ ions or by the loss of HCO₃⁻. Addition of H⁺ may occur as a result of exogenous administration or endogenous production of acids associated with pathologic states. Loss of bicarbonate occurs primarily through gastrointestinal or renal wasting, with acidosis being produced by driving the equilibrium reaction to the left:

H⁺ + HCO₃⁻ ⇌ H₂CO₃ ⇌ CO₂ + H₂O

As discussed previously, the initial response to acidosis is extracellular and intracellular buffering, combined with respiratory compensation via increased alveolar ventilation. These protective mechanisms attempt to minimize free H⁺ within the system until a full renal response excretes the excess acid load.

It is important to remember that compensatory responses do not fully normalize pH. If a normal pH is seen in a patient with metabolic acidosis, a second acid-base disorder must be present. The typical laboratory pattern of metabolic acidosis is decreased pH and bicarbonate with a compensatory decrease in PCO₂ (Box 160.5).

Enhanced alveolar ventilation is triggered through pH-mediated stimulation of peripheral chemoreceptors. Minute
ventilation is augmented via increased tidal volume (hyperpnea) and later followed by an increased respiratory rate (tachypnea), depending on the degree of acidosis. The expected Pco₂ is calculated by the following equation:

$$\text{Pco}_2 = 1.5 \times (\text{HCO}_3^-) + 8 \pm 2$$

This equation assesses the adequacy of respiratory compensation. A Pco₂ that is significantly higher or lower than this calculated value signals the presence of a secondary respiratory acidosis or alkalosis, which may have a profound impact on treatment decisions (Box 160.6).

This protective effect lasts only a few days, however, because the chronically diminished Pco₂ paradoxically signals renal bicarbonate wasting. The final effect is that arterial pH in chronic metabolic acidosis is the same, with or without respiratory compensation.

Causes of metabolic acidosis are classified according to the presence or absence of an elevated AG. However, even in the absence of an AG, there may be accumulation of unmeasured anions.

Non-AG acidoses are those that add HCl to the system. The acid anion in these cases is chloride; because of its inclusion in the AG equation, no change in the gap is noted. The most common causes of non-AG acidosis include renal and gastrointestinal bicarbonate wasting (Box 160.7).

**METABOLIC ALKALOSIS**

Metabolic alkalosis is characterized by the net gain of base equivalent, as reflected by elevated plasma bicarbonate. Direct proton loss from extracellular fluid produces an elevation in serum bicarbonate by shifting the following equilibrium reaction to the right:

$$\text{H}_2\text{CO}_3 \rightarrow \text{H}^+ + \text{HCO}_3^-$$

The elevated plasma pH produces compensatory hypoventilation to increase Pco₂. Because serum pH is determined by the ratio of HCO₃⁻ to Pco₂ and not by the absolute HCO₃⁻ level, this compensatory response acts to minimize the change in serum pH.

Metabolic alkalosis is the second most common acid-base disorder and is found in approximately one third of hospitalized patients. It can be caused by several processes: increased H⁺ loss, typically through renal or gastrointestinal wasting; increased bicarbonate resorption; infusion or ingestion of bicarbonate; intracellular shifts in H⁺; or contraction of extracellular fluid around a stable HCO₃⁻ pool (Box 160.8).

Because of the kidneys’ ability to excrete excess HCO₃⁻, maintenance of metabolic alkalosis requires impairment of this process. The majority of the filtered bicarbonate is reclaimed in the proximal tubule, with approximately 10% of HCO₃⁻ being reabsorbed in the distal segments. Type B cells in the cortical collecting tubule may also actively secrete excess bicarbonate. Maintenance of metabolic alkalosis requires failure of these mechanisms. This generally results from contraction of extracellular volume, which stimulates Na⁺ retention and enhanced activity of the Na⁺-H⁺ antipporter in the proximal tubule.

Hyperaldosteronism induced by extracellular fluid depletion also plays a role in maintaining alkalosis by increasing H⁺ secretion in the distal nephron through activation of H⁺-transporting adenosine triphosphatase (H⁺-ATPase). Hypokalemia and hyperaldosteronism maintain the alkalosis through stimulation of proximal and distal bicarbonate resorption, transcellular exchange of K⁺ and H⁺, and increased ammoniagenesis.

The most frequent causes of metabolic alkalosis are loss of gastric secretion and use of diuretics. Loss of gastric secretion generates an equimolar gain in HCO₃⁻ for the lost H⁺. Likewise, loss of gastric secretion is associated with a contracted...
metabolic alkalosis because of the slow movement of charged 

cellular signs and symptoms are uncommon in patients with 

decreased ionized calcium as a result of alkalemia. Neuro-

neuromuscular irritability are observed, probably related to 

coma, seizure, carpopedal spasm, respiratory depression, and 

to the associated volume contraction. Weakness, fatigue, 

cate a superimposed respiratory acidosis or alkalosis.

Compensation rarely results in a P value greater than 55 mm Hg. Significant deviations from this compensatory response indicate a superimposed respiratory acidosis or alkalosis. The signs and symptoms of alkalosis are commonly related to the associated volume contraction. Weakness, fatigue, coma, seizure, carpopedal spasm, respiratory depression, and neuromuscular irritability are observed, probably related to decreased ionized calcium as a result of alkalalemia. Neuromuscular signs and symptoms are uncommon in patients with metabolic alkalosis because of the slow movement of charged HCO₃⁻ into the CNS.

Urine chloride helps determine the cause and treatment of the metabolic alkalosis. Urine chloride levels less than 20 mEq/L indicate appropriate renal chloride avidity and imply that the source of the metabolic alkalosis is extrarenal. Accordingly, fluid and chloride repletion is the mainstay of therapy in these saline- or chloride-responsive conditions. In contrast, urine chloride levels higher than 40 mEq/L indicate renal chloride wasting and implicate altered renal function at a source of the metabolic alkalosis.

volume of extracellular fluid, which maintains alkalosis through volume depletion and hyperaldosteronism. Diuretics also induce an alkalosis through secondary hyperaldosteronism associated with hypovolemia, hypokalemia, and enhanced distal H⁺ secretion.

The respiratory compensation for metabolic alkalosis is variable. On average, Pco₂ can be predicted as follows:

\[ \text{Pco}_2 = 0.6 \times \text{HCO}_3^- \]

Compensation rarely results in a Pco₂ greater than 55 mm Hg. Significant deviations from this compensatory response indicate a superimposed respiratory acidosis or alkalosis.

The signs and symptoms of alkalosis are commonly related to the associated volume contraction. Weakness, fatigue, coma, seizure, carpopedal spasm, respiratory depression, and neuromuscular irritability are observed, probably related to decreased ionized calcium as a result of alkalalemia. Neuromuscular signs and symptoms are uncommon in patients with metabolic alkalosis because of the slow movement of charged HCO₃⁻ into the CNS.

Urine chloride helps determine the cause and treatment of the metabolic alkalosis. Urine chloride levels less than 20 mEq/L indicate appropriate renal chloride avidity and imply that the source of the metabolic alkalosis is extrarenal. Accordingly, fluid and chloride repletion is the mainstay of therapy in these saline- or chloride-responsive conditions. In contrast, urine chloride levels higher than 40 mEq/L indicate renal chloride wasting and implicate altered renal function at a source of the metabolic alkalosis.

Loss of Hydrogen
Gastrointestinal
- Vomiting, nasogastric suction
- Antacid therapy
- Bulimia
- Chloride-losing diarrhea (villous adenoma)
Renal
- Loop and thiazide diuretics
- Mineralocorticoid excess (hyperaldosteronism, drug or medication)
- Cushing disease
- Bartter syndrome
- Gitelman syndrome
- Chronic hypercapnia
- Low chloride intake
- High-dose carbenicillin
- Hypercalcemia, milk-alkali syndrome

Intracellular H⁺ Shift
Massive blood transfusion
NaHCO₃ administration
Milk-alkali syndrome

Contraction Alkalosis
Loop or thiazide diuretics
Gastric loss
Sweat loss (cystic fibrosis)

In summary, the treatment of metabolic alkalosis should be directed at the underlying cause. Once the cause is identified, specific therapy is required to correct the alkalosis. In the absence of an underlying cause, treatment should focus on restoring the normal pH balance by correcting the electrolyte imbalances. Intravenous sodium bicarbonate can be used to correct the alkalosis, but it is often the case that other measures are required to address the underlying cause. In general, the treatment of metabolic alkalosis should be guided by a careful assessment of the patient’s history, physical examination, and laboratory findings.
maintenance factor that should be reversed with potassium chloride. The total body potassium deficit may be profound and is often underappreciated.

Saline-resistant alkaloses display excessive mineralocorticoid activity, such as hyperaldosteronism, Cushing syndrome, and renal artery stenosis. Treatment of saline-resistant causes (urine chloride >20 mEq/L) is directed at the other causes of the metabolic alkalosis. Potassium deficits should be corrected by supplementation or direct antagonism of aldosterone with agents such as spironolactone. In patients with metabolic alkalosis and concomitant edematous states (e.g., congestive heart failure, cirrhosis, nephrotic syndrome), acetazolamide enables bicarbonate and volume excretion.

Alcoholic Ketoacidosis

Christopher R. Carpenter

Alcoholic Ketoacidosis accounts for up to 20% of cases of ketoacidosis.

The characteristic example is an alcoholic person who abruptly abstains and has signs and symptoms such as vomiting, abdominal pain, malnutrition, and an anion gap metabolic acidosis, but no measurable alcohol levels.

Initial glucose levels may be low, normal, or high.

A ratio of β-hydroxybutyrate to acetoacetate in excess of 10:1 is pathognomonic for alcoholic ketoacidosis, whereas a 3:1 ratio is more common in diabetic ketoacidosis.

Treatment emphasizes hydration with dextrose-containing solutions and thiamine; resolution of the acidosis usually occurs within 6 to 12 hours.

Mortality from uncomplicated alcoholic ketoacidosis is less than 1%.

DEFINITION AND EPIDEMIOLOGY

The diagnosis of alcoholic ketoacidosis (AKA) is established when an alcoholic patient is found to have an anion gap metabolic acidosis without historical or laboratory evidence suggesting an alternative cause. AKA may develop after protracted vomiting in malnourished, chronic alcoholics who consume a daily average of 200 g of ethanol. AKA generally occurs with equal frequency in adult men and women between 20 and 60 years of age. Its incidence and prevalence remain undefined. Up to one half of patients are likely to suffer recurrence. It is unclear whether these individuals have a genetic predisposition to AKA or whether they repeatedly reproduce the hormonal milieu that precipitates ketoacidosis. Almost one fifth of cases of ketoacidosis are alcoholic ketoacidosis.

PATHOPHYSIOLOGY

The term alcoholic acidosis describes a syndrome of four types of metabolic acidosis that occur in alcoholics and vary in severity: ketoacidosis, lactic acidosis, acetic acidosis, and loss of bicarbonate in urine. AKA arises from a complicated interplay of the metabolic effects of alcohol in fasted, dehydrated alcoholics who abruptly stop their intake of ethanol.

β-Hydroxybutyrate is the predominant ketoacid. Metabolism of ethanol to acetaldehyde is catalyzed by alcohol dehydrogenase in the liver and results in accumulation of the reduced form of nicotinamide adenine dinucleotide (NADH) relative to the oxidized form of nicotinamide adenine dinucleotide (NAD\(^+\)). The altered ratio of NADH/NAD\(^+\) is the rate-limiting step in alcohol metabolism and favors the conversion of acetoacetate to β-hydroxybutyrate, as illustrated in Figure 161.1.

Impaired insulin effects, dehydration, and hormonal responses propagate the accumulation of ketoacid. Ethanol consumption, acute starvation, and catecholamine release cause a relative insulin insufficiency that acts to favor lipolysis and limit glycogen storage. The formation of ketone bodies is further promoted by a dehydration-induced stress response–related release of cortisol, growth hormone, glucagons, and catecholamines. It is unclear whether the elevated levels of cortisol and growth hormone observed in patients with AKA initiate or sustain this process. Ketone bodies in the form of β-hydroxybutyrate are produced as a result of the NADH/NAD\(^+\) ratio induced by ethanol metabolism, as well as the lipolytic effect of counterregulatory hormones. Renal excretion of ketone bodies becomes impaired because of dehydration, volume contraction, and diminished renal clearance. Accumulation of ketoacid ensues.

Lactic acidosis is a common, concurrent acid-base disorder, in addition to ketoacidosis. Although lactic acidosis may result from another cause such as sepsis or seizures, alcohol consumption can cause mild accumulation of lactic acid by two distinct mechanisms. First, the elevated NADH/NAD\(^+\) ratio can shift the pyruvate–lactic acid equilibrium in favor of lactic acidosis. Second, the thiamine deficiency common in chronic alcoholics prohibits the alternative oxidation of pyruvate to acetyl coenzyme A because thiamine is a coenzyme in this reaction.

PRESENTING SIGNS AND SYMPTOMS

AKA typically develops in severe alcoholics whose recent binge drinking has abruptly and recently stopped. The sudden alcohol cessation is often due to an alcohol-related disease.
such as gastritis, pancreatitis, hepatitis, or pneumonia. Concurrent starvation, abdominal pain, and protracted vomiting are common features.

Patients typically have a clear sensorium, are not confused, and are able to provide a complete history, although there are case reports of encephalopathic manifestations. Box 161.1 summarizes the sensitivity of signs and symptoms for AKA.

Tachycardia and tachypnea are typically the most remarkable findings on examination. Tachycardia results from volume depletion and early alcohol withdrawal, whereas tachypnea is generally a physiologic response to the ongoing metabolic acidosis. Hypotension and hypothermia are rare. Fever usually indicates a separate, concurrent infectious process. Abdominal examination may reveal hepatomegaly, hepatic tenderness, epigastric discomfort, or severe and diffuse tenderness. The presence of hypotension, fever, peritoneal signs, bloody stools, trauma, or altered mental status mandates a search for alternative causes of these physical findings.
Alcoholic patients are predisposed to a variety of complications that may precipitate AKA, including gastritis, peptic ulcer disease, Boerhaave syndrome, pancreatitis, and hepatitis. In addition, intoxicated patients are at increased risk for infectious complications such as aspiration pneumonia. Evaluation for alcohol-related conditions should occur in parallel with evaluation and management of presumed AKA.

### DIFFERENTIAL DIAGNOSIS

AKA is one of the many conditions that cause an anion gap metabolic acidosis, which is partly summarized by the mnemonic CAT-MUDPILES, as shown in the Tips and Tricks box. When an anion gap is present, an osmolar gap can help distinguish between these various entities. Additional rare causes of an anion gap metabolic acidosis include sulfuric acidosis, short bowel syndrome, formaldehyde, nalidixic acid, methemamine mandelate, rhubarb ingestion, and inborn errors of metabolism such as the methylmalonic acidemias.

### FACTS AND FORMULAS

\[
S_I = \frac{S_V}{BSA}
\]

\[
\text{Osmolar gap} = \left[2 \left(\frac{\text{Na}^+}{2}\right) + \frac{\text{glucose}}{18} + \frac{\text{BUN}}{2.8} + \frac{\text{EtOH}}{4.6}\right]
\]

An osmolar gap greater than 25 mOsm/kg is specific for methanol or ethylene glycol.

A β-hydroxybutyrate level greater than 386 μmol/L has been proposed as a forensic pathology cutoff to identify “ketoalcoholic death.” Levels higher than 2500 μmol/L can be fatal.

### TIPS AND TRICKS

“CAT-MUDPILES” Mnemonic
- C = Carbon monoxide, Cyanide
- A = Alcoholic ketoacidosis
- T = Toluene
- M = Methanol*
- U = Uremia
- D = Diabetic ketoacidosis
- P = Paraldehyde, Phenformin
- I = Iron, Isoniazid
- L = Lactic acidosis
- E = Ethylene glycol*
- S = Salicylates, Strychnine, Starvation

*Osmolar gap, greater than 25 mOsm/kg.

The acid-base disorder in AKA is usually a mixed anion gap metabolic acidosis and respiratory alkalosis. pH ranges from 6.7 to 7.6, and the anion gap ranges from 20 to 40. Hypoalbuminemia is common in alcoholics and may lower the observed anion gap.

Glucose levels may be low, normal, or elevated. Diabetic alcoholics with modest elevations in glucose (>250 mg/dL) pose a particular diagnostic challenge because they may have diabetic ketoacidosis (DKA) or concurrent DKA and AKA. A useful distinguishing feature in these cases is the β-hydroxybutyrate–acetacacetate ratio, which is 1:1 normally, 3:1 with DKA, and 10:1 with AKA.

Because the nitroprusside reaction used in a urine dipstick tests for DKA, a negative urine dipstick test for “ketones” does not exclude AKA. In such instances, the dipstick may show paradoxic worsening of urine ketones as AKA resolves with treatment and β-hydroxybutyrate is converted to acetacacetate.

Hypokalemia and hypophosphatemia are common with AKA, particularly as treatment progresses. Alcohol levels are generally zero, although case reports have noted the presence of AKA even when ethanol is detectable.

### TREATMENT

Treatment of AKA is directed at correcting three deficits: volume depletion, glycogen depletion, and the elevated NADH/NAD⁺ ratio. Intravenous fluid and glucose are highly effective treatments. Administration of dextrose-containing solutions to hypoglycemic or euglycemic patients stimulates NADH oxidation and replaces glycogen stores, which results in more rapid correction of acidosis than with saline alone. Antiemetics should be provided.

Initially normal levels of magnesium, potassium, and phosphorus decrease during treatment and require repletion. Intravenous thiamine supplementation (100 mg) provides theoretic prophylaxis against Wernicke encephalopathy and may help reverse the lactic acidosis. Exogenous insulin and bicarbonate therapy is rarely indicated.

### DISPOSITION

Mortality in patients with AKA is less than 1%. Adverse outcomes are typically associated with concurrent alcohol-related complications rather than with the ketoacidosis itself. Admission for uncomplicated AKA is indicated for patients with intractable vomiting or abdominal pain of unclear cause.
If a thorough evaluation fails to reveal additional acute health issues, the acidosis can be treated and resolved within 6 to 12 hours. Discharged patients should have appropriate follow-up to address issues of chronic alcohol abuse. Patients may also benefit from an alcohol rehabilitation program (see Chapter 199). Discharge instructions should advise patients of their predisposition for recurrent episodes of AKA, as well as the potentially detrimental effect of alcohol abuse on other aspects of their health. Return precautions should include intractable vomiting, caloric starvation, and increasing abdominal pain.

More than 23 million individuals in the United States have diabetes mellitus, and this number continues to increase at an accelerated rate, partially because of the worsening obesity epidemic in this country. In almost 6 million of these individuals, however, the diabetes is undiagnosed. In addition to the cost of life and morbidity associated with this disease, the financial expense is enormous. In 2007 the estimated direct and indirect cost of treating diabetes mellitus in the United States was $116 billion and $58 billion, respectively.\(^1\)

**STRUCTURE AND FUNCTION**

Insulin is a 51–amino acid protein produced by the beta cells of the islet of Langerhans in the endocrine pancreas. After the initial protein, proinsulin, is translated on the rough endoplasmic reticulum, it is cleaved serially first to proinsulin and then to insulin and C peptide. Insulin and its C peptide are stored in a 1:1 ratio in secretory granules and released primarily in response to glucose and, to a lesser extent, amino acids. Release can be further potentiated or inhibited by a number of gastrointestinal and systemic hormones.

On release, insulin binds to its membrane-spanning receptor. Binding induces a conformational change in the structure of the receptor so that it becomes enzymatically active; it is now a functional tyrosine kinase that can initiate anabolic pathways.

A newer classification system of diabetes mellitus reflects the pathophysiology of the disease and long-term treatment options. The new system identifies four types of diabetes mellitus: type 1, type 2, gestational diabetes, and “other” (Table 162.1).

Type 1 diabetes mellitus (note the Arabic numbering) has replaced older terms such as type I, insulin-dependent, and juvenile-onset diabetes mellitus. These older terms became confusing for a multitude of reasons. For example, a small subset of “type II” diabetics fail oral hypoglycemic treatment and must be treated with an insulin regimen; are these patients “insulin dependent”? With increasing worldwide childhood obesity, more and more childhood diabetics are being seen who are not “insulin dependent,” and yet their disease cannot be classified as “adult onset.”

Type 1 diabetes mellitus can best be defined as an absolute deficiency of insulin. The mechanism is complex and occurs in approximately 5% of all patients with diabetes mellitus. The process usually begins years before symptoms appear when the patient is exposed to an antigen (e.g., viral infection) that is similar in structure to a protein found in islet beta cells. The immune system begins to produce a humoral and cell-mediated assault on these antigens that leads to progressive destruction of the cells. Destruction of beta cells results in a decrease in insulin levels, and eventually a critical point is

---

**KEY POINTS**

- Type 1 diabetes mellitus is defined as an absolute deficiency of insulin and type 2 as a relative insulin deficiency. These terms replace older definitions.
- The primary treatment modality for hyperglycemic emergencies is hydration with normal saline. In patients with diabetes, insulin therapy must follow evaluation of electrolyte levels.
- The majority of ketones in patients with diabetic ketoacidosis consist of β-hydroxybutyrate, but standard laboratory tests evaluate for acetoacetate. Hence, the standard “ketone” studies may not reflect this disease process.
- Intravenous bolus insulin has no role in any hyperglycemic condition or emergency, including diabetic ketoacidosis.
- Subcutaneous insulin is the preferred route for the treatment of hyperglycemia. A continuous intravenous insulin infusion may be warranted in patients with severe emergency conditions such as diabetic ketoacidosis; however, subcutaneous insulin has been suggested to be as efficacious for mild to moderate disease.
- Patients with diabetic ketoacidosis have a significant potassium deficit and require supplementation.
- Intravenous administration of dextrose-containing fluid should be initiated in patients with diabetic ketoacidosis when their glucose level is at or below 250 mg/dL to minimize the risk for hypoglycemia.
reached at which insulin requirements are no longer met and hyperglycemia ensues.

The other categories include patients with relative insulin deficiency; it is important to note that the majority of hyperglycemic patients in the remaining groups do produce insulin, and thus it is easier to conceptualize their insulin deficiency as a balance between insulin and other counterregulatory hormones (e.g., epinephrine, glucagon, cortisol, growth hormone).

Type 2 diabetes mellitus has replaced older terms such as type II, non–insulin-dependent, and adult-onset diabetes mellitus. The process leading to this type of diabetes also begins years before the onset of overt clinical symptoms. For a multitude of reasons, most commonly obesity, peripheral tissues become increasingly resistant to the effects of insulin. Such resistance leads to increased production of insulin by beta cells, which allows years of relative glucose control. Eventually, the relative insulin resistance can no longer be met by increasing beta cell production, and the patient begins to experience hyperglycemia. Additionally, the beta cells may begin to “burn out” and ultimately produce progressively less and less insulin. The onset of clinical symptoms may be insidious in an otherwise healthy patient or abrupt when significant illness produces a spike in the counterregulatory hormones (e.g., epinephrine, glucagons, cortisol, growth hormone) that tends to increase plasma glucose levels. This abrupt onset occurs because a type 2 diabetic is not able to increase insulin production to counteract this rise, as would a nondiabetic.

The third category is gestational diabetes mellitus, which occurs in about 2% to 5% of all pregnancies, most often in the second or third trimester. It is believed to occur in a manner similar to that of type 2 diabetes. Pregnancy induces increased levels of human placental lactogen, estrogen, and cortisol—all hormones that tend to increase plasma glucose levels. Pregnant women are usually able to produce insulin in sufficient quantities to combat this increase in glucose-elevating hormones; however, susceptible women cannot. This condition most often resolves after delivery, but as one would expect, these women are susceptible to the development of type 2 diabetes later in life. Gestational diabetes mellitus can cause fetal complications, mostly as a result of increased fetal plasma glucose levels. In response to this elevated glucose derived via placental blood, the fetal pancreas increases plasma insulin production, which results in increased fetal birth weight.

The fourth category—“other”—is a catchall that contains all other causes of diabetes mellitus, including genetic anomalies causing malfunctioning insulin protein, insulin receptors, and beta cells in general, as well as other immune-mediated causes. Any significant insult to the exocrine pancreas—be it trauma, chronic pancreatitis, or cystic fibrosis—may result in this type of diabetes. Many common drug-induced causes of diabetes mellitus fall into this category (Box 162.1), as well as endocrinopathies such as hyperthyroidism, Cushing syndrome, and pheochromocytoma. Infectious causes include congenital rubella and cytomegalovirus. Less common causes include genetic disorders that may be associated with diabetes mellitus, including Down syndrome, Klinefelter syndrome, Turner syndrome, Prader-Willi syndrome, Huntington chorea, and porphyria.

### CLINICAL PRESENTATION

The signs and symptoms of diabetes mellitus can be quite varied. The classic manifestations are discussed here, but it is important to note that many patients do not have these symptoms. Typically, patients with type 1 diabetes have had years of progressively decreasing insulin secretion as a result of beta cell destruction. However, most often an infection or other stressor acutely increases levels of the counterregulatory hormones and the patient is unable to counter this spike with an insulin surge. Hyperglycemia (generally defined as a fasting glucose level > 126 mg/dL) then ensues, and the patient suddenly seeks care in the emergency department (ED).

As the plasma glucose level increases and eventually surpasses the threshold of the kidneys to reabsorb glucose, the patient begins to spill glucose into urine. This leads to osmotic diuresis and ensuing polyuria and polydipsia.
DIAGNOSTIC TESTING

All patients with a history of diabetes mellitus should have an early point-of-care glucose assay performed when seen in the ED. At a minimum, diabetic patients with systemic complaints or complaints common to hyperglycemia require glucose testing at the time of first assessment. It is important to note that if serial tests are to be performed, there is a small but significant difference between capillary and venous blood glucose levels. Additionally, any patient with altered mental status or new neurologic concerns should also have glucose levels tested because patients with hypoglycemia or hyperglycemia may exhibit these changes.

The purpose of laboratory testing in a hyperglycemic patient is to differentiate simple hyperglycemia from DKA and less commonly from HHS. It is important to note that no reliable historical or physical examination findings are sensitive or specific enough to confirm or exclude these acute and serious complications of diabetes in hyperglycemic patients. A bicarbonate level below 15 mmol/L with an elevated anion gap (varies depending on the laboratory, but the upper limit is generally approximately 16 mEq/L) strongly suggests DKA. A more complete laboratory evaluation for hyperglycemia includes venous pH, β-hydroxybutyrate (BHB), and possibly serum osmolality. Additional laboratory tests may be necessary as dictated by the clinical picture. It has recently been suggested that acetoacetate (ACA), the standard ketone assayed for by serum and urine “ketone” assays, is neither sensitive nor specific for the diagnosis of DKA.

DIAGNOSIS AND DIAGNOSTIC TESTING

The purpose of laboratory testing in a hyperglycemic patient is to differentiate simple hyperglycemia from DKA and less commonly from HHS.

It is important to ascertain the probable cause of the hyperglycemia. Although dietary indiscretion and medication non-compliance do play a role, these diagnoses should be considered only after excluding more serious causes. The most concerning causes can be grouped into two classes: infection and infarction.

Complete a thorough evaluation for possible sources of infection in all diabetic patients. Chest radiography is indicated to search for pneumonia in patients with historical and physical examination findings suggesting pneumonia, patients in whom a thorough history and physical examination cannot be obtained, clinically ill patients, and patients at the extremes of age.

Infarction-related causes of hyperglycemia include acute coronary syndrome (acute myocardial infarction and unstable angina), pulmonary embolism, and cerebrovascular accident. It is important to note that acute coronary syndrome is very likely to be manifested in an atypical manner in diabetic patients (e.g., new-onset congestive heart failure without any history of chest pain or dyspnea without chest pain). Any hyperglycemic patient with these findings should undergo a complete ED evaluation for acute coronary syndrome. A computed tomography scan of the brain or chest may be required if cerebrovascular accident or pulmonary embolism is a concern.

TREATMENT

Patients with significant hyperglycemia, diabetic ketoacidosis (DKA), or hyperglycemic hyperosmolar state (HHS) are almost universally dehydrated and intravascularly depleted. Even though this is certainly more so in the latter two conditions, all conditions require hydration. The initial treatment is intravenous (IV) hydration with normal saline (NS). Insulin is not the initial treatment of these diabetic complications.

HYPERGLYCEMIA

PATHOPHYSIOLOGY

Hyperglycemia ensues when the endocrine pancreas cannot produce enough insulin to decrease plasma levels of glucose appropriately (>126 mg/dL in a fasting patient). In type 1 diabetes, this is due to an absolute deficiency; in the other types of diabetes, it is due to a relative deficiency of insulin in comparison with the levels of counterregulatory hormones. In this way, glucose levels increase in plasma and eventually overwhelm the renal glucose threshold, thereby resulting in spillage of glucose into urine. By osmosis, water is pulled into urine, which leads to increased urination and dehydration. This in turn leads to increased thirst and polydipsia. The degree of hyperglycemia and dehydration varies greatly from patient to patient and even in the same patient on different occasions.

Because hyperglycemia is most often associated with some degree of dehydration, the primary modality of treatment should be rehydration with NS. Early insulin therapy is contraindicated before determining electrolyte levels. After the patient is significantly rehydrated, laboratory studies have excluded additional complications such as DKA, and electrolyte status has been stabilized, subcutaneous insulin can be administered.

IV bolus administration of insulin has no role in the treatment of hyperglycemia. Administration of insulin via a continuous drip is not indicated, except in very special circumstances in which exceedingly tight glucose control is required (e.g., during a progressing cerebral vascular accident) for the treatment of simple hyperglycemia. In fact, very tight glucose control in an ill patient has been suggested to have no effect on patient outcome other than significantly increased rates of hypoglycemia. The dose of insulin depends on the degree of hyperglycemia after hydration and the patient’s previous exposure to insulin therapy. Patients with known diabetes treated with insulin therapy may be given their usual dose after hydration. Patients new to insulin may be given low-dose subcutaneous insulin with the goal of decreasing glucose to acceptable levels at a rate of 100 mg/dL/hr.

A guideline for subcutaneous regular insulin dosing is presented in Table 162.2. This guideline is appropriate for hyperglycemic patients who have little to no previous experience with subcutaneous insulin. Those managed with insulin
regimens may do better with one approximating their typical dosage. In addition, this guideline assumes that the patient has first been rehydrated and remains hyperglycemic.

It is important to note that euglycemia may not be a realistic or even appropriate goal in these patients while they are in the ED; longer-term (over a period of days to weeks) personalization of an insulin or oral hypoglycemic regimen by the patient’s primary care provider or inpatient physician is preferred. The ED goal may be simply to rehydrate the patient and then use subcutaneous insulin to further decrease the patient’s glucose level. Targeting a “normal glucose” level in patients new to insulin therapy is fraught with risks, mostly notably hypoglycemia. Moreover, no target “maximum allowable glucose level” before discharge of the patient has been established.

NEW-ONSET TYPE 2 DIABETES

Box 162.2 summarizes the clinical and diagnostic findings in patients with new-onset diabetes. In the past these patients were admitted to the hospital without question and a new drug or insulin regimen started. This practice has changed in the last decade because it is now recognized that medications can be started in the outpatient setting without exposing these patients to the inherent risks associated with hospitalization.

TREATMENT AND DISPOSITION

The initial medication for patients with new-onset diabetes is most often a low-dose sulfonylurea. A good choice of sulfonylurea is glyburide (1.25 to 2.5 mg orally once a day) or glipizide (2.5 to 5 mg orally once a day). These doses may not allow strict glucose control but are appropriate early therapy and pose little risk for hypoglycemia. When starting these medications, patients should be instructed to take them with an early meal or breakfast and to eat regular meals throughout the day. Metformin (850 mg orally once a day) is an appropriate choice for initiating diabetes therapy when a nonsulfonylurea drug is preferred. This drug, when used alone in initial therapy, poses a very low risk for hypoglycemia and may be a good choice for obese patients.10

All patients with new-onset diabetes should have follow-up arranged in an expedited manner. Patients with comorbid conditions or acute disease should be admitted for inpatient evaluation and treatment.

DIABETIC KETOACIDOSIS

The signs and symptoms of patients with DKA seen in the ED can be incredibly variable. For this reason it is important to remember that although there is a classic manifestation of DKA, there are no typical findings. The emergency physician should not be lulled into a false sense of security by a hyperglycemic patient who “looks good.” DKA should be considered a spectrum of disease, and patients can progress from “looking good” to “being ill” very quickly. Thus any patient in the ED with hyperglycemia requires a laboratory evaluation.4

EPISTEMOLOGY

The approximate incidence of DKA is 5 to 8 cases per 1000 diabetics per year. Mortality has remained approximately 4% to 5% for the last decade in patients in whom DKA is diagnosed and treatment begun early in the disease course. Some estimates of mortality in patients in whom diagnosis and treatment are delayed run as high as 14%.11 Other estimates suggest that in as many as 20% of patients DKA is misdiagnosed; these patients therefore have a significantly increased risk for death.

PATHOPHYSIOLOGY

A hyperglycemic patient has a deficiency in insulin; type 1 diabetics have an absolute deficiency and type 2 diabetics have a relative deficiency. When this deficiency is significant,
patients are unable to uptake glucose from blood into cells and must rely on the metabolism of fat for energy. Fatty acids from blood are metabolized in the liver to three ketone bodies: ACA, BHB, and acetone. Acetone is a minor component and may be removed from the body via the lungs; this is often manifested as a fruity odor on the breath. The other ketone bodies are in equilibrium with their ratio determined by the redox state and relative levels of nicotinamide adenine dinucleotide (NAD) to NADH (the reduced form of NAD); consequently, the majority of ketones generated during DKA are in the form of BHB. The increasing level of BHB causes an acidosis and leads to significant electrolyte shifts, including shift of potassium out of cells into blood. Because of the continued hyperglycemia, the patient experiences hyperglycemic osmotic diuresis, which leads to significant renal potassium loss and total body potassium depletion. The acidosis also causes a decrease in serum bicarbonate levels and eventually overwhelms this buffering system and results in decreased serum pH.

These changes lead to the classic findings of DKA, including dehydration, Kussmaul breathing (deep, sighing type of respiration caused by acidosis-induced stimulation of the central respiratory center, which may be seen in other forms of acidosis), abdominal discomfort, vomiting, and often altered mental status.

**CLINICAL PRESENTATION**

The causes of DKA are many, and they are similar to those of hyperglycemia (Box 162.3). The onset may be due to any significant stressor (classically an infection or infarction) or may be due to a deficiency of insulin, usually because the insulin dosage is insufficient, oral therapy is ineffective, or the patient is not compliant with therapy. It is important to note that diabetic patients may have acute conditions—for example, patients with diabetes and pneumonia—and may therefore need increased insulin administration temporarily or DKA will develop; in these cases the cause of the ketoacidosis is both infection and inadequate insulin administration.

**Differential Diagnosis, Diagnostic Testing, and Testing Pitfalls**

The differential diagnosis of DKA is summarized in Box 162.4. In any patient who may have DKA, the laboratory evaluation shown in Box 162.5 should be performed. No single standard laboratory diagnosis has been established for DKA; however, any diagnosis should include the factors noted in Box 162.6. It should be stressed that the diagnosis of DKA is based mainly on clinical findings; although laboratory evaluation is important, common complicating factors often make
laboratory diagnosis difficult. Each of the components of the laboratory diagnosis is fraught with limitations and qualifications.

Hyperglycemia is commonly considered the cornerstone of the work-up; however, DKA in the presence of “euglycemia” is not an uncommon finding. In fact, approximately 30% of patients with DKA have a glucose level lower than 300 mg/dL, and some studies suggest that the longer patients are in a state of DKA, the more likely they are to be euglycemic. The reasons for this are manyfold. Patients with DKA often have gastrointestinal disturbances that cause vomiting and therefore limited oral intake, with the result that liver glyco-

genate stores will be depleted and gluconeogenesis, which may be inhibited during acidosis, will be the sole source of glucose production. It has also been suggested that patients with poorly controlled diabetes do not store glucose as well as do nondiabetic individuals or patients whose disease is well controlled. Liver disease of any cause will also limit or prevent glycogen storage and gluconeogenesis.

Acidosis, or decreased serum bicarbonate, and an elevated anion gap are the basic components of the diagnosis. Patients with DKA often vomit considerably and lose acid through this mechanism. They can also become exceptionally dehydrated, which leads to stimulation of the renin-angiotensin system and promotes the loss of both potassium and hydrogen ion in the distal tubule of the kidneys. Medications such as diuretics and antacids may also cause a metabolic alkalosis.

Although the majority of patients have a low serum bicar-

boxrate and pH, as well as an elevated anion gap, approximately 10% will have at least one of these factors reported as normal. It should be noted that venous pH is perfectly acceptable and there is no reason to obtain an arterial sample.

The final component of the diagnosis is the presence of ketones. As discussed previously, the majority of ketones are in the form of BHB, but the standard laboratory urine and serum examinations assay for ACA. Recent work has sug-

ggested that ACA is neither sensitive nor specific for DKA, whereas BHB appears to be very sensitive and specific for this disease. Additionally, ACA levels may not be high enough to be detected, especially in the dilute urine of a patient experi-

cing hyperglycemic osmotic diuresis. However, as the patient is rehydrated and treatment begins, serum BHB is converted to ACA. Thus, in a not-uncommon scenario, a hyperglycemic patient is initially negative for urine ketones but after rehydration and treatment begins to “suddenly spill” them and is falsely labeled as worsening and beginning to be in DKA when in fact the patient already was in DKA but the diagnosis was missed because the urine examination tested for the “wrong” ketone.

### TREATMENT

A treatment plan for DKA is outlined in Box 162.7. Early treatment is similar to that for hyperglycemia. Patients usually exhibit moderate to severe dehydration and should receive NS. The average patient without a history of congestive heart failure or renal failure often requires 5 to 8 L of fluid over the

<table>
<thead>
<tr>
<th><strong>BOX 162.7 Treatment Plan for Patients with Diabetic Ketoacidosis</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>This regimen is recommended for the average adult patient and must be tailored to the individual patient. Patients in whom volume overload is a concern (e.g., with a history of congestive heart failure or renal impairment) may need more gentle hydration. Those with a greater degree of dehydration may require greater amounts of normal saline (NS).</strong></td>
</tr>
<tr>
<td><strong>Intravenous Fluids</strong></td>
</tr>
<tr>
<td>Administer 2 L NS over first 1 to 2 hours; a third liter may be administered over an additional hour.</td>
</tr>
<tr>
<td>Change from NS to ½ NS after the patient’s clinical hydration status begins to improve (usually after 2 to 3 L).</td>
</tr>
<tr>
<td>Change from ½ NS to D5 ½ NS when the patient’s glucose level reaches 250 mg/dL.</td>
</tr>
<tr>
<td><strong>Electrolytes</strong></td>
</tr>
<tr>
<td>No insulin should be given until the patient’s potassium level is known.</td>
</tr>
<tr>
<td>Potassium replacement (oral administration is preferred, but the intravenous route can be used if the patient cannot tolerate oral replacement) should be started as follows:</td>
</tr>
<tr>
<td>• K+ higher than 5.0 mEq/L—no acute replacement needed.</td>
</tr>
<tr>
<td>• K+ 3.5 to 5.0 mEq/L—give a single oral dose of 40 mEq/L of KCl.</td>
</tr>
<tr>
<td>• K+ lower than 3.5 mEq/L—give two oral doses of 40 mEq/L of KCl. Ensure that K+ is 3.5 mEq/L or higher before starting insulin.</td>
</tr>
<tr>
<td><strong>Insulin</strong></td>
</tr>
<tr>
<td>Intravenous bolus insulin has no role in the treatment of diabetic ketoacidosis.</td>
</tr>
<tr>
<td>After the patient is hemodynamically stable, start a regular insulin drip at 0.05 to 0.1 U/kg/hr. Early evidence suggests that mild to moderate diabetic ketoacidosis may be treated with insulin subcutaneously. When the patient’s anion gap has resolved to less than 15 mEq/L, administer a long-acting insulin (e.g., glargine) subcutaneously at the patient’s usual dose or as below:</td>
</tr>
<tr>
<td>• Calculate the total insulin units given by the intravenous route over the last 4 hours. Multiply this total by 6, which equals the total 24-hour dose (T24D) of insulin needed.</td>
</tr>
<tr>
<td>• T24D × 0.5 = units of insulin glargine to give subcutaneously now.</td>
</tr>
<tr>
<td>• Turn insulin infusion off 2 hours after glargine insulin has been given subcutaneously.</td>
</tr>
<tr>
<td>• The remaining total daily dose of insulin is given as a prandial short-acting insulin (aspart or lispro) divided into three doses.</td>
</tr>
<tr>
<td>• Example: A patient received 12 units of regular insulin intravenously over the last 4 hours. Multiply 12 × 6 = 72 units T24D. Give half the total daily dose as glargine; therefore, 36 units of glargine insulin is given subcutaneously. The remaining units (36) are divided by three and given as 12 units aspart subcutaneously with three meals.</td>
</tr>
</tbody>
</table>
course of the hospitalization. Potassium levels must be checked and hypokalemia corrected concurrent with the administration of insulin because patients may have significant (often hundreds of milliequivalents) total body potassium depletion. Insulin will drive extracellular potassium into cells and, because of the total body depletion, may cause an exaggerated serum hypokalemia that may lead to cardiac arrhythmia.

Other electrolytes such as magnesium and phosphorus are less crucial and may be administered as usual. Correction of even moderate hypophosphatemia has not been shown to be beneficial in these patients. It is therefore recommended that only severe hypophosphatemia (<1 mmol/L) or moderate hypophosphatemia with clinical findings such as respiratory muscle weakness or cardiomyopathy be corrected. If necessary, potassium chloride may be replaced with potassium phosphate for this purpose. Hypomagnesemia may be corrected with IV magnesium sulfate.

Bicarbonate therapy rarely has a place in the treatment of patients with DKA. Although administration of bicarbonate to a patient with metabolic acidosis may seem logical, it is rarely helpful and may cause multiple, significant complications. Because bicarbonate cannot cross the blood-brain barrier but carbon dioxide can, administration of bicarbonate may allow increased carbon dioxide to enter cerebrospinal fluid and cause a paradoxical cerebrospinal fluid acidosis. Additionally, bicarbonate administration may worsen the hypokalemia by driving potassium into cells. Studies have clearly shown administration of bicarbonate to a patient with DKA and a pH of at least 6.8 to be of no benefit. No studies specifically support the administration of bicarbonate for any pH in patients with DKA. If bicarbonate administration has any role, it may be only in a patient with shock and impending or present cardiovascular collapse secondary to marked acidosis and dehydration.

Administration of insulin should begin only after the initial hydration and electrolyte correction. IV bolus insulin has no role in treatment. Administration of IV bolus insulin leads to a supraphysiologic serum insulin level that can cause a significant drop in plasma potassium levels and cardiac arrhythmias. It may also cause hypoglycemia and cerebral and pulmonary edema, and it has been theorized to lead to changes in gene-regulated protein synthesis that may exert its effects for weeks. Additionally, because IV regular insulin has a plasma half-life of less than 5 minutes, a continuous, low-dose infusion reaches a steady-state level quickly.

The standard insulin protocol has been to start a drip of regular insulin at 0.1 U/kg. More recently it has been suggested that lower doses may work as well with less risk for hypokalemia, and some authors have even suggested the use of subcutaneous insulin.

Patients treated by insulin drip are at risk for hypoglycemia and hypokalemia, as mentioned previously, and therefore require regular electrolyte and glucose assays. The author recommends alternating a bedside glucose assay with a basic chemistry panel every hour and charting a flow sheet as shown in Table 162.3. Potassium can then be supplemented as necessary. The patient’s fluid should be changed to D5/2 NS (5% dextrose solution in 1/2 NS) when the glucose level reaches 250 mg/dL. When the anion gap has resolved to 15 mEq/L or less, the patient should be given subcutaneous insulin at the usual dose or at a dose similar to those detailed in Box 162.7. Two hours later, the insulin drip can be discontinued; this approach allows subcutaneous insulin administration and the insulin drip to overlap by 2 hours.

It is not necessary nor should it be expected for the pH to return to normal before discontinuing the insulin drip. Because the treatment regimen by itself will often cause hyperchloremic acidosis, monitoring the anion gap is more helpful than monitoring the pH. In a patient with normally functioning kidneys, the chloride level and pH will then be slowly corrected over a period of hours to days. In a patient who has otherwise recovered, mild acidosis at this point should not prevent discharge.

Cerebral edema has long been the most feared complication of pediatric DKA. It occurs in approximately 1% of all cases but carries a mortality rate quoted to be as high as 50%. It has long been held that the treatment regimen, especially rapid rehydration, has been responsible for this complication.

However, no data support this belief, and the current literature strongly suggests that there is no causal relationship between cerebral edema in pediatric patients with DKA and their treatment regimen\(^1\); instead, it is more likely that the degree of illness better correlates with the likelihood of this deadly complication. Treatment is similar to that for other causes of cerebral edema while the standard management of DKA continues.

### DISPOSITION

All discharged patients should begin an insulin regimen. Oral hypoglycemic medications are insufficient after treatment of DKA.

Patients being treated with an insulin drip need to be monitored closely for all the reasons discussed previously; they are usually admitted to an intensive care unit or other specialized unit that can closely monitor their glucose, electrolytes, and clinical status.

If patients with DKA are hungry and have no other contraindication, they should be allowed to eat. Eating a normal meal will decrease the likelihood of hypoglycemia and hypokalemia.

### HYPERGLYCEMIC HYPEROSMOLAR STATE

HHS is a comparatively uncommon but nonetheless serious complication of diabetes mellitus, with a mortality rate as high as 50%.\(^2\) It has had many other names in the past, including hyperosmolar nonketotic coma, hyperglycemic hyperosmolar coma, and hyperosmolar nonacidotic diabetes mellitus. The term hyperglycemic hyperosmolar state is more appropriate because not all patients with HHS are nonketotic and certainly not all are in coma or have altered mental status.\(^2\)

### PATHOPHYSIOLOGY

Like DKA, HHS is initiated by a relative lack of insulin; however, the insulin deficiency is usually significantly less profound than that of DKA. Very low levels of insulin (or a low ratio of insulin to counterregulatory hormones) are necessary to prevent ketoacidosis; as insulin levels increase, further gluconeogenesis and glycogen metabolism are sequentially switched off. Because just small amounts of insulin are needed to prevent ketosis, only limited amounts of ketones are produced during HHS. The patient becomes successively more dehydrated secondary to the glucose-driven osmotic diuresis. The dehydration may eventually lead to impaired renal function and an inability to excrete the continually produced glucose, thereby resulting in severe hyperglycemia.\(^2\)

### CLINICAL PRESENTATION

Typically, these patients may state that they cannot or do not wish to drink liquids; patients with HHS may thus have an impaired thirst sensation or may be unable to obtain water (e.g., elderly or bedridden, psychiatric, or jailed patients).

Despite many similarities between DKA and HHS, they differ in some very important ways (Table 162.4). As discussed earlier in regard to DKA, patients with HHS may often have atypical findings. The diagnosis of HHS is associated with glucose levels higher than 600 mg/dL, but the average glucose level is approximately 900 mg/dL, and it is not uncommon for the glucose level to be well in excess of 1000 mg/dL.

### DIAGNOSTIC TESTING AND TESTING PITFALLS

Diagnostic criteria for HHS are summarized in Box 162.8. As with DKA, it needs to be stressed that the diagnosis is based mainly on clinical findings; although laboratory evaluation is important, common complicating factors often make laboratory diagnosis difficult.

When considering the diagnosis, any treatment before collection of samples for laboratory tests must be noted. These patients are severely dehydrated and hyperglycemic; any fluid administration—for example, by the emergency medical service—will significantly decrease their glucose level. In this context it is not uncommon for HHS to be diagnosed in
patients with an initial glucose level of just 500 mg/dL. Serum osmolarity may also decrease to a lesser degree with initial fluid resuscitation.

Absence of ketosis is required to differentiate pure HHS from pure DKA. However, many patients lie in a spectrum between these two entities and may form a small amount of BHB. Additionally, because most laboratories actually assay for ACA, as discussed earlier, mild ketoacidosis is common secondary to anorexia and vomiting. Another classic finding of HHS is a “normal pH.” However, it is not uncommon to have a mild acidic hyperosmolar state secondary to lactic acidosis caused by lack of perfusion to peripheral tissues from the severe dehydration. In fact, approximately one half of patients with HHS are believed to have a mild anion gap metabolic acidosis.28 In addition, the pH may temporarily decrease further during the initial fluid resuscitation as the peripherally produced lactic acid is returned to the liver for processing.

**TREATMENT**

A treatment plan for HHS is summarized in Box 162.9. As with simple hyperglycemia and DKA, the primary treatment is fluid resuscitation with NS. The average fluid deficit is 9 L.29 Resuscitation includes administration of boluses of 1 to 2 L of NS initially, followed by administration of NS until there is improvement in vital signs that suggests improved hemodynamics, as indicated by the onset of urine output and an improved clinical hydration state. Fluids then can be changed to $\frac{1}{2}$ NS.

Failure to change the fluid at this point is apt to lead to significant and clinically detrimental hypernatremia. Fluid administration can be guided further by the following:

1. Patients should have approximately 50% of their fluid deficit met in the first 12 hours of treatment.
2. Glucose levels should fall no faster than 100 mg/dL/hr after the initial resuscitation is completed.

Electrolytes also require aggressive monitoring and replacement. Total body deficits of potassium, magnesium, and phosphate cannot be gauged accurately from the initial laboratory assays and should be supplemented aggressively once urine output has been established. Note that although the initial measured potassium may be normal or even high, the patient is still severely potassium depleted. Therefore, potassium supplementation must be started early in the course of

---

**BOX 162.9 Treatment Plan for Patients with Hyperglycemic Hyperosmolar State**

- **Potassium replacement** (oral administration is preferred, but the intravenous route can be used if the patient cannot tolerate oral replacement) should be started as follows:
  - $K^+$ higher than 5.0 mEq/L—no acute replacement is needed.
  - $K^+$ 3.5 to 5.0 mEq/L—give a single oral dose of KCl, 40 mEq/L.
  - $K^+$ lower than 3.5 mEq/L—give two oral doses of KCl, 40 mEq/L. Ensure that the $K^+$ level is 3.5 mEq/L or higher before starting insulin.

- **Magnesium replacement**—unless the patient is in renal failure and not able to produce urine, early administration of magnesium is mandatory:
  - Begin intravenous piggyback (IVPB) administration of 2 g of MgSO$_4$ over a 2-hour period and continue administration over the course of treatment.
  - Magnesium must be supplemented along with phosphate to prevent the development of clinically significant hypocalcemia.

- **Phosphate replacement**
  - Potassium phosphate can be substituted for a portion of the potassium chloride.

- **Patients being treated for HHS are at risk for refeeding syndrome and should receive thiamine supplementation.**
  - An initial IVPB dose of 100 mg of thiamine in the emergency department is an appropriate early intervention.

- When the patient has clinically improved with a glucose level lower than 300 mg/dL, intravenous insulin may be switched to subcutaneous insulin in a manner similar to that for diabetic ketoacidosis (see Box 162.7).
treatment and certainly before the initiation of any insulin therapy.

Phosphate and magnesium supplementation may be more essential in the management of HHS than in the treatment of DKA. Because HHS characteristically develops over a period of days to weeks, total body stores of these electrolytes are more likely to have been significantly affected by the osmotic diuresis. Although compelling studies are lacking, it is probably of greater urgency to supplement these electrolytes early in the course of treatment.30,37

Insulin administration should begin only after the patient has been fluid-resuscitated to the point of hemodynamic stability and potassium replacement has been started. Insulin has no role in the initial treatment of HHS—early administration can lead to cardiovascular collapse.

The effective osmolarity of the vasculature in patients with HHS is dependent on the high level of glucose present. This level may decrease slowly with the administration of NS as sodium begins to replace glucose in maintaining proper tonicity. However, if insulin is administered early before appropriate NS resuscitation is attained, this cannot happen. Insulin will drive glucose intracellularly, thereby effectively and quickly decreasing intravascular tonicity, which may lead to acute and catastrophic cardiovascular collapse. Additionally, early insulin administration will drive potassium intracellularly and risk the same hypokalemia-induced arrhythmias discussed earlier in the treatment of DKA.

After early fluid and electrolyte administration and when the patient is hemodynamically stable, insulin therapy can begin. Typically, a drip of regular insulin is started at 0.05 to 1 U/kg/hr; many authorities suggest low doses of 2 to 4 U/hr. This is then titrated to control the rate of decrease in glucose to approximately 50 to 100 mg/dL/hr. As with DKA and hyperglycemia, IV bolus administration of insulin has no role in the treatment of HHS.

**DISPOSITION**

Patients should be admitted to the intensive care unit because frequent neurologic examinations and regular laboratory studies are required during the first 24 hours of treatment. Electrolyte supplementation will need to be adjusted regularly based on the results of these laboratory tests. As with patients with DKA, if patients being treated for HHS are hungry, their mental status has returned to baseline, and no other contraindications are present, there is no reason that they should not eat. They are often ravenously hungry, and eating will act naturally to decrease the likelihood of hypoglycemia and acute electrolyte deficiencies.

Hypoglycemia

Wesley H. Self and Candace D. McNaughton

“low blood glucose” has not been firmly established because of variations in the concentration at which different people begin to experience symptoms, but a blood glucose concentration lower than 60 mg/dL is generally considered abnormally low.

EPIDEMIOLOGY

Patients who use insulin or oral hypoglycemic medications are at the greatest risk for hypoglycemia. These patients experience mild, self-treated hypoglycemic episodes about twice per week. Severe hypoglycemia, which requires the assistance of another person to regain euglycemia, is experienced at least once per year by 27% of patients treated with intensive insulin regimens. Hypoglycemia is the cause of death in approximately 3% of people with insulin-dependent diabetes. Patients taking oral hypoglycemic agents also commonly experience hypoglycemia. Although these episodes are generally associated with milder symptoms, they occur in more than 30% of patients each year. Sulfonylureas are the most widely used oral hypoglycemic agents. In 2004, 4148 sulfonylurea overdoses were reported to American poison control centers; of these, 36% occurred in children younger than 6 years, 21% required treatment of hypoglycemia, 2.5% were life-threatening, and 0.22% were fatal. The incidence of hypoglycemia is expected to rise as tight glycemic control continues to be emphasized for the 17 million Americans with diabetes.

Hypoglycemia in nondiabetic patients is quite rare and should raise concern about the possibility of a severe underlying illness, alcohol ingestion, or inappropriate exposure to insulin or an oral hypoglycemic agent.

NORMAL GLYCEMIC CONTROL

INSULIN

Unlike other organs, the brain cannot synthesize glucose or store a significant glycogen supply and therefore requires an uninterrupted flow of glucose from the bloodstream for normal function and survival. Under normal physiologic conditions, the blood glucose concentration is maintained within a narrow range (70 to 110 mg/dL) through a balance of catabolic processes that increase blood glucose and anabolic processes that decrease blood glucose. Insulin, a protein released

This work was supported by the Office of Academic Affiliations, Department of Veterans Affairs, VA National Quality Scholars Program with resources and use of the facilities at VA Tennessee Valley Healthcare System, Nashville, TN.
from pancreatic beta cells in response to rising blood glucose levels, is the hormone responsible for initiating anabolic glucose metabolism. It promotes glycolysis, inhibits glycogenolysis and gluconeogenesis in the liver, inhibits proteolysis in skeletal muscle, and inhibits lipolysis and promotes lipogenesis in adipose tissue. Insulin secretion is inhibited during fasting to maintain euglycemia and essentially ceases when the blood glucose concentration falls below 80 mg/dL.

COUNTERREGULATORY HORMONES

The hormones glucagon, epinephrine, cortisol, and growth hormone promote catabolic glucose metabolism as part of the counterregulatory response and oppose the actions of insulin. When the blood glucose concentration drops below 65 to 70 mg/dL, glucagon is secreted from pancreatic alpha cells, and epinephrine is released from the adrenal medulla and sympathetic neurons. These hormones inhibit the entry of glucose into cells, stimulate glycogenolysis and gluconeogenesis, mobilize amino acids to act as gluconeogenic precursors, activate lipolysis, and inhibit insulin secretion.

Glycogenolysis increases blood glucose within minutes and can maintain euglycemia in a well-nourished person for 24 hours. Gluconeogenesis requires several hours to raise blood glucose levels and is the principal mechanism responsible for maintaining euglycemia if fasting is extended beyond 24 hours. Secretion of cortisol from the adrenal cortex and growth hormone from the anterior pituitary gland is a delayed response to blood glucose falling below 60 to 65 mg/dL; these hormones are not involved in the correction of acute hypoglycemia but act to maintain euglycemia over a period of days to weeks.6,7

A clinically important consequence of the counterregulatory response is the Somogyi phenomenon. A nighttime insulin dose that is too large causes hypoglycemia during sleep, and the counterregulatory response causes rebound hyperglycemia at the morning glucose check. Increasing the nighttime insulin dose in response to morning hyperglycemia will cause dangerous overnight hypoglycemia and exacerbate the morning hyperglycemia. Paradoxically, decreasing the nighttime insulin dose in this case would lower the morning blood glucose concentration and is the appropriate treatment.

Many of the symptoms of hypoglycemia are caused by an acute increase in glucagon (which causes nausea, vomiting, and abdominal pain) and epinephrine (which causes anxiety, trembling, palpitations, tachycardia, and sweating). The hypoglycemic symptoms caused by epinephrine, called autonomic or hyperepinephrinic symptoms, function as a warning that mild hypoglycemia has developed; the patient can then correct the hypoglycemia by eating before neurologic impairment ensues. Hypoglycemia unawareness, or the development of hypoglycemia without the normal autonomic symptoms to warn the patient, increases the risk for severe hypoglycemia.

Patients with type 1 and advanced (insulin-dependent) type 2 diabetes may have an impaired counterregulatory reaction. In these patients, the glucagon response is often nonexistent and the epinephrine response is greatly attenuated.5 This impaired counterregulatory response predisposes patients to severe hypoglycemia by blunting the glycemic response to falling blood glucose levels and thereby leaving the patient with no early warning symptoms of hypoglycemia. Furthermore, even one episode of hypoglycemia blunts the epinephrine response to future hypoglycemia and can result in hypoglycemia-associated autonomic failure.9 In this manner a vicious cycle of recurrent hypoglycemia can develop. Avoidance of hypoglycemia for several weeks improves hypoglycemia awareness and restores the epinephrine component of the counterregulatory response.5

CAUSES OF HYPOGLYCEMIA

Hypoglycemia occurs in patients with a relative excess of insulin in comparison with the hormones of the counterregulatory response. Such excess can occur through the administration of exogenous insulin, an increase in endogenous insulin, or inhibition of the counterregulatory response. This section highlights the most important causes of hypoglycemia, the mechanisms by which they act, and the context in which they are likely to be observed in the emergency department (ED) (Table 163.1).

EXOGENOUS INSULIN AND ORAL HYPOGLYCEMIC AGENTS

Administration of insulin or an oral hypoglycemic medication is the most common cause of hypoglycemia. In a patient with diabetes who is being treated with an established regimen of insulin or an oral hypoglycemic medication, hypoglycemia can develop for a number of reasons (Table 163.2).

Oral hypoglycemic medications include the sulfonylurea and meglitinide drug classes, both of which increase endogenous pancreatic secretion of insulin. Other classes of antihyperglycemic oral medications, including biguanides, α-glucosidase inhibitors, and thiazolidinediones, do not increase insulin levels and do not induce hypoglycemia when used in isolation. However, when used in addition to insulin or an oral hypoglycemic medication, these medicines can precipitate hypoglycemia that is more refractory to treatment.

The time to peak effect and duration of action of insulin preparations and oral hypoglycemic medications dictate management and disposition (Table 163.3). Patients often cannot reliably recall which type of insulin they use; a helpful characteristic is that glargine and all rapid- and short-acting insulins are clear liquids whereas neutral protamine Hagedorn (NPH) and Ultralente appear cloudy.

Diabetes caused by chronic pancreatitis is associated with a concomitant deficiency of glucagon because of the loss of pancreatic alpha cells, thus making these patients very susceptible to the hypoglycemic effects of insulin and oral hypoglycemic medications. These medications can also cause hypoglycemia in a nondiabetic patient when taken accidentally, in a suicide attempt, or as part of a factitious disorder or Munchausen by proxy syndrome. Factitious disorder and Munchhausen by proxy syndrome should be considered in cases of unexplained hypoglycemia in healthy patients, especially in female health care workers and family members of a person with diabetes.

ADDITIONAL CAUSES OF HYPOGLYCEMIA

Alcohol ingestion (ethanol), the second most common cause of hypoglycemia in the ED, inhibits the counterregulatory response by suppressing hepatic gluconeogenesis. It has minimal effects on glycogenolysis. Therefore, alcohol

</table>

ACE, Angiotensin-converting enzyme; ED, emergency department; EDTA, ethylenediaminetetraacetic acid; HELLP, hemolysis elevated liver enzymes, and low platelet count.
Alcohol is a major factor in hypoglycemia, occurring in 50% of cases. In the ED, hypoglycemic episodes seen in lower settings can occur in otherwise healthy people. Insulinomas are rare, with an incidence of 4 per 1 million per year. Early diagnosis is important because these tumors are curable with surgery.

Non-islet cell tumors, including hepatomas, carcinoids, sarcomas, and melanomas, can cause hypoglycemia by several mechanisms: a paraneoplastic syndrome caused by secretion of insulin-like growth factors, multiple metastases to the liver with impaired hepatic function, massive tumor burden with increase metabolic demand for glucose, and production of autoantibodies to insulin or the insulin receptor. Autoantibodies that augment the effects of insulin can also occur in conjunction with autoimmune diseases such as systemic lupus erythematosus and Graves disease.

Vague autonomic symptoms after eating were once labeled postprandial hypoglycemia, alimentary hypoglycemia, or functional hypoglycemia. This poorly understood mimic of hypoglycemic symptoms has never been linked to depressed blood glucose concentrations. However, after gastric surgery, including gastric bypass, gastrectomy, and pyloroplasty, patients can experience a true postprandial or alimentary hypoglycemia. Traditionally, the mechanism was thought to be rapid emptying of carbohydrates into the small intestine causing an exaggerated insulin response, or dumping syndrome. Recent evidence suggests that Nesidioblastosis (beta-cell hyperplasia causing hyperinsulinism) plays a role in postprandial hypoglycemia following gastric surgery.

Medications other than those used for the treatment of diabetes have been associated with hypoglycemia (see Table 163.1). Quinine, quinidine, pentamidine, and disopyramide stimulate release of insulin from pancreatic beta cells and have the potential to cause severe hypoglycemia. Commonly used drugs that may cause hypoglycemia include salicylates (mechanism unknown), acetaminophen (hypoglycemia occurs only in overdose with liver damage), angiotensin-converting enzyme (ACE) inhibitors (the mechanism may involve increased insulin sensitivity), and beta-blockers (inhibit the counterregulatory response of epinephrine). ACE inhibitors and beta-blockers typically cause hypoglycemia only when used concomitantly with insulin or oral hypoglycemic agents. Nonselective beta-blockers (e.g., propranolol) have more hypoglycemic potential than do selective beta-blockers (e.g., metoprolol) and can occasionally cause hypoglycemia in the absence of antidiabetic medications, especially in children.

CAUSES OF HYPOGLYCEMIA IN PEDIATRIC POPULATIONS

Children are predisposed to hypoglycemia because they have small glycogen stores and a large brain-to-body mass ratio. Neonates are at significant risk for hypoglycemia as a result of developmental immaturity of gluconeogenesis and ketogenesis combined with temporary impairment of glycogenolysis because of the stress of delivery. Neonates of mothers with poorly controlled diabetes are further predisposed to hypoglycemia as a result of the hyperinsulinemia induced by maternal hyperglycemia. Additionally, inborn errors of metabolism, such as glucose-6-phosphatase deficiency, galactosemia, and carnitine deficiency, can be manifested as hypoglycemia in neonates.

Gastroenteritis increases the risk for hypoglycemia by decreasing intestinal absorption of carbohydrates and by increasing metabolic demands of the illness. Reid and Losek found that 9% (18 of 196) of children aged 1 month to 5 years seen in an ED with gastroenteritis and dehydration had hypoglycemia, although none of the children exhibited altered mental status.

Idiopathic ketotic hypoglycemia is the most common cause of clinically significant hypoglycemia in nondiabetic children aged 7 months to 5 years. This syndrome is characterized by fasting intolerance and may be caused by a deficiency of alanine, an amino acid substrate for gluconeogenesis. During a 10- to 16-hour fast, the counterregulatory response converts triglycerides to ketone bodies and causes a mild metabolic...
acidosis and ketonuria, but it fails to maintain euglycemia. Affected children tend to be slender but not malnourished, with weight percentile below height percentile. These children often have a concurrent illness and are seen in the ED in the morning with a blood glucose concentration of 35 to 60 mg/dL, bicarbonate value of 14 to 19 mmol/L, and ketonuria. The syndrome typically remits by 6 years of age as lean body mass and alanine levels increase.

CLINICAL PRESENTATION

The signs and symptoms in patients with hypoglycemia are divided into two categories: those caused by elevated levels of glucagon and epinephrine as part of the counterregulatory response (autonomic or hyperepinephrinemic symptoms) and those caused by insufficient supply of glucose to the brain (neuroglycopenic symptoms). Autonomic symptoms typically appear when the blood glucose concentration drops below 60 mg/dL and include anxiety, irritability, nausea, vomiting, palpitations, trembling, flushing, hunger, and sweating. Neuroglycopenic symptoms emerge below a blood glucose concentration of 50 mg/dL and include inability to concentrate, inattention, headache, lethargy, dizziness, blurry vision, agitation, confusion, and focal neurologic deficits. When the blood glucose concentration drops below 30 mg/dL, seizures and coma may ensue. Permanent brain damage and death are rare but occur when the hypoglycemia is severe and left untreated. Predicting who will have permanent neurologic impairment is difficult in the ED, but elderly patients, those with concurrent hypoglycemia, and in particular those with previous strokes are vulnerable to incomplete recovery.

The signs and symptoms of hypoglycemia are not uniformly present with each episode. Recurrent episodes in the same person tend to be symptomatically similar, but hypoglycemia can be manifested differently among individuals. Variations include the blood glucose threshold at which symptoms develop, the severity of symptoms at a given glucose concentration, the predominance of certain symptoms, and their order of appearance. The severity of neuroglycopenic symptoms depends on many factors other than the nadir of blood glucose, including the patient’s general state of health and age; integrity of the counterregulatory response; and the severity, duration, timing, and number of previous hypoglycemic episodes. For example, Osoria et al. showed that nondiabetic, neurologically normal people who were administered exogenous insulin to decrease their blood glucose concentration to 30 mg/dL experienced only subtle neuroglycopenic symptoms and no alteration in consciousness. Hypoglycemic episodes blunt the symptoms of future hypoglycemia. Therefore, lower blood glucose concentrations with recurrent episodes will be symptomatically silent and predispose the patient to repeated severe hypoglycemia, which can cause cumulative cognitive decline.

Other than previous hypoglycemic episodes, additional features that increase the risk for hypoglycemia in diabetic patients include the use of insulin, longer duration of insulin use, higher doses of insulin, glycosylated hemoglobin values that are initially high and fall rapidly with therapy, adolescent age, and male gender. Use of an insulin pump does not alter the risk for hypoglycemia when compared with multiple daily insulin injections.

DIFFERENTIAL DIAGNOSIS

The signs and symptoms of hypoglycemia are associated with a long list of diagnoses. The causes of hypoglycemia create an equally long list (see Tables 163.1 and 163.2).

Hypoglycemia should be considered in any patient with an acute neurologic abnormality, however obvious or subtle, especially if it involves an alteration in mental status. Classic examples include a diabetic patient who collapses during exercise, an alcoholic patient with seizures, and patients in coma after an overdose of oral medications. More challenging findings include strokelike focal neurologic deficits, psychotic-like bizarre and combative behavior, and septicilike hypotonia and lethargy in an infant. Hypoglycemia should be included in the differential diagnosis of each of the following diseases: stroke, transient ischemic attack, seizure, traumatic brain injury, narcolepsy, multiple sclerosis, psychosis, and drug intoxication.

Furthermore, the blood glucose concentration should be checked in all patients requiring ED resuscitation because critical illness can cause hypoglycemia. Losek found that 18% (9 of 49) of pediatric patients undergoing nontraumatic ED resuscitation were hypoglycemic. Additionally, hypoglycemia should be considered in all accidental and intentional drug ingestions, in children with prolonged vomiting and diarrhea, and in all diabetics encountered in the ED.

DIAGNOSTIC TESTING

GLUCOMETRY

The optimal method for diagnosing hypoglycemia is rapid determination of the blood glucose concentration through point-of-care testing with a bedside glucometer. Bedside glucometers measure the concentration of glucose in whole blood, whereas laboratory tests measure the glucose concentration in plasma or serum. Because of the relative paucity of glucose in blood cells, whole blood concentrations of glucose are approximately 15% lower than plasma concentrations. Newer models of bedside glucometers calculate an estimated plasma glucose concentration based on the measured whole blood concentration. Although bedside glucometers that undergo routine quality control have adequate accuracy to direct immediate therapy, laboratory tests of glucose concentration are more accurate than bedside glucometers, especially in the extreme high and low ranges of blood glucose concentration.

The accuracy of bedside glucometry and laboratory tests of serum glucose concentration can be compromised by several mechanisms. Bedside glucometers are less accurate with hematocrit levels above 55 or below 30 because of variations in the relative amount of blood cells and plasma. Artificially low serum glucose measurements are seen with hemolytic anemia (nucleated red blood cells consume glucose in the collection tube), with leukemia (leukocytes consume glucose), and when blood is collected in a tube lacking a glycolysis-suppressing agent such as fluoride. An artificially high glucose concentration may be reported by bedside glucometry during an acetaminophen overdose because of interference with the measuring technique.
If a symptomatic patient does have a low glucose concentration by bedside glucometer, a blood sample should be drawn as early as possible for the following laboratory tests: glucose, insulin, C peptide, proinsulin, glucagon, growth hormone, cortisol, β-hydroxybutyrate, insulin antibodies, and sulfonylurea drug levels. This so-called critical blood sample will be essential later, after the patient’s ED course, for determining the cause of the hypoglycemia. The critical blood sample is most important for the evaluation of first-time occurrences of hypoglycemia; recurrent cases of medication-induced hypoglycemia do not require such extensive testing.

Treating the hypoglycemia before obtaining the critical blood sample will limit its usefulness, but in a life-threatening situation, the first duty of the emergency physician (EP) is to reverse the hypoglycemia and only secondarily to facilitate a diagnostic evaluation.

**TREATMENT**

Stabilization of a patient with hypoglycemia begins with the primary assessment. A bedside glucose measurement should be obtained, intravenous (IV) access secured, supplemental oxygen initiated, and a cardiac monitor applied. Intubation should not proceed until hypoglycemia has been treated because treatment of hypoglycemia may completely restore baseline mentation.

Treatment of hypoglycemia involves repletion of blood glucose via oral or IV administration of exogenous glucose or glucagon administration to stimulate endogenous glucose production. The specific treatment modality depends on the patient’s age, whether the patient’s mental status allows safe oral ingestion, and whether IV access can be established (Fig. 163.2).
METHODS OF ADMINISTRATION

**Oral Administration**

Oral repletion of glucose is appropriate if the patient can eat without risk for aspiration. An initial oral dose is 15 g of a simple carbohydrate such as glucose, fructose (fruit juice), or sucrose (table sugar). Dextrose is the \(d\)-isomer of glucose and for practical purpose can be considered synonymous with glucose. Commercially available oral glucose products include tablets (4 to 5 g per tablet), gels (15 to 45 g per tube), and nutritional bars (15 to 24 g per bar). Alternatively, an equivalent carbohydrate dose can be given as 6 oz of regular soda or juice or 1 tablespoon of honey, jelly, or table sugar.

\(\alpha\)-Glucosidase inhibitors (acarbose, miglitol) interrupt the intestinal absorption of oral sucrose; therefore, if oral repletion is planned for a patient taking one of these medications, sucrose products, including soda, candy, and table sugar, should be avoided in favor of glucose products. Oral repletion with simple carbohydrates increases the blood glucose concentration within minutes and lasts about 20 minutes.

**Intravenous Administration**

If a patient’s mental status prohibits oral repletion and IV access cannot be obtained, an IV dextrose bolus is the treatment of choice. The IV dose in adults is 1 ampule of 50% dextrose in water (D\(_{50}\)W), which contains 25 g of glucose it may be repeated up to three times. The increase in blood glucose concentration in response to 1 ampule of D\(_{50}\)W is unpredictable; it ranges from about 40 to 350 mg/dL and averages about 160 mg/dL. The glycemic response to a bolus of dextrose peaks within 5 minutes and lasts about 30 minutes.\(^{30,31}\)

Because hypertonic solutions such as D\(_{50}\)W sclerose small veins, children younger than 8 years should be given IV D\(_{25}\)W as a bolus of 2 to 4 mL/kg. Infants should be given IV D\(_{10}\)W, 5 to 10 mL/kg. These doses deliver 0.5 to 1 g of glucose per kilogram of body weight. As in adults, repeated boluses of dextrose are appropriate if an incomplete response is seen.

The rare complications of dextrose administration include hypokalemia, hypophosphatemia, dilutional hyponatremia, and fluid overload. Electrolyte levels should be monitored if repeated boluses or continuous infusions are given.

**Intramuscular Administration**

If oral glucose repletion is not possible and IV access cannot be established, intramuscular (IM) or subcutaneous (SC) glucagon becomes the treatment of choice. IM or SC dosing is 1 mg of glucagon for adults, 0.5 mg for children younger than 8 years, and 50 mcg/kg for infants. Glucagon stimulates glycogenolysis and reverses the symptoms of hypoglycemia after about 10 minutes; the peak glycemic response occurs in 30 minutes and the duration of action is 1 to 2 hours. Glucagon can be repeated after 10 minutes if neurologic recovery is incomplete, but dextrose is preferred if IV access can be established in the interim.

Glucagon is ineffective in patients with depleted glycogen stores, including alcoholic, malnourished, and elderly patients. Adverse effects include significant nausea and vomiting about 60 minutes after administration, so protection of the airway from vomiting and potential aspiration is a priority if mental status does not improve.

**MONITORING AND REPEATED GLUCOSE ADMINISTRATION**

The glycemic response to oral carbohydrates, IV dextrose, and glucagon is transient. It is essential to monitor for signs of recurrent hypoglycemia and recheck glucose levels every 30 minutes for 4 hours after euglycemia is achieved. The patient
Hypoglycemia caused by short-acting insulin, alcohol, and idiopathic ketotic hypoglycemia usually responds rapidly to initial replacement and does not recur. Recurrent hypoglycemia is expected when the cause of the hypoglycemia is ongoing, as with sulfonylureas, long-acting insulin, and critical illness. In these cases, continuous IV infusion of dextrose is often necessary.

**ADJUNCTIVE TREATMENTS**

**Octreotide**

Octreotide is used as a supplemental treatment of sulfonylurea- and insulinoma-induced hypoglycemia. It is a synthetic analogue of the hormone somatostatin and a potent inhibitor of pancreatic insulin secretion. Although octreotide does not treat existing hypoglycemia, it can prevent recurrent hypoglycemia and reduce the amount of dextrose supplementation needed. In sulfonylurea-induced hypoglycemia, octreotide should be used instead of continuous dextrose infusions and glucagon whenever possible because dextrose and glucagon stimulate further insulin secretion from the sulfonylurea-primed pancreatic beta cells.

The most effective octreotide dose has not been established. One recommended adult dose is 50 to 100 mcg of SC octreotide every 6 hours; continuous IV infusions of octreotide (100 to 125 mcg/hr) have also been used successfully. A recommended pediatric dose is SC octreotide, 4 to 5 mcg/kg/day divided every 6 hours. No significant side effects of octreotide have been demonstrated when used for hypoglycemia.

**Diazoxide**

Diazoxide, a rarely used antihypertensive medication, also inhibits pancreatic insulin secretion and can be used for sulfonylurea-induced hypoglycemia. It is considered a second-line therapy in comparison with octreotide because of lower efficacy and greater risk for toxicity. Side effects include hypotension and sodium retention. The IV adult dose is 300 mg of diazoxide given over a 1-hour period; the IV pediatric dose is 1 to 3 mg/kg given over a 1-hour period. Doses can be repeated every 4 hours as needed.

**Other Adjunctive Treatments**

When hypoglycemia is caused by a massive overdose of SC insulin, one case report suggests that needle aspiration or surgical excision of the SC reservoir may reduce the systemic absorption of insulin.

Early administration of activated charcoal is indicated for sulfonylurea overdose and accidental pediatric sulfonylurea ingestion. Maximum efficacy is achieved if the charcoal is given within 1 hour of the ingestion. Glipizide undergoes enterohepatic circulation; peak plasma concentrations may be decreased by multiple doses of activated charcoal. Because of the delayed peak effects of extended-release glipizide, whole-bowel irrigation can be considered for overdoses of this preparation.

Urine alkalization can reduce the half-life of chlorpropamide from 49 hours to 13 hours through increased renal excretion. However, urine alkalization does not appear to be useful in reducing the duration of effect of other hypoglycemic agents.

**RISKS ASSOCIATED WITH PRESumptive TREATMENT**

It has been suggested previously that dextrose be given to all patients with undifferentiated altered mental status as part of the “coma cocktail,” which consists of oxygen plus IV administration of 1 ampule of D5W, 100 mg of thiamine, and 0.4 mg of naloxone. This practice was challenged in the 1980s when animal and retrospective human studies suggested that hyperglycemia may be detrimental to the injured brain, particularly in the setting of acute stroke, cardiac arrest, hypotension, and head trauma. The true risk of administering a small glucose load to a euglycemic or hyperglycemic patient with a brain injury has not been established but is thought to be small. Hypoglycemia, in contrast, is known to be detrimental, especially to the injured brain. Therefore, the current recommendation is to obtain a bedside glucose measurement in patients with altered mental status and administer dextrose only when the blood glucose level is lower than 60 mg/dL. Treatment should be initiated empirically only when a glucometer is not immediately available.

Traditional teachings also warn that dextrose should never be given to patients with altered mentation without a preceding dose of thiamine because of the risk of precipitating Wernicke encephalopathy. Thiamine is a cofactor for two essential reactions in the glycolysis–tricarboxylic acid cycle (conversion of pyruvate to acetyl coenzyme A and α-ketoglutarate to succinate). Theoretically, without adequate supplies of thiamine, the energy contained in glucose cannot be converted to adenosine triphosphate, so substrates for the thiamine-dependent reactions accumulate in the brain and cause Wernicke encephalopathy. Administering dextrose to a thiamine-deficient patient increases the production of these substrates, but no clinical evidence has shown that a dextrose load dosed to reverse hypoglycemia precipitates Wernicke encephalopathy if thiamine is not given first. When treating a patient with altered mental status and confirmed hypoglycemia or with possible hypoglycemia without access to a bedside glucometer, EPS should administer thiamine and dextrose simultaneously if possible. Dextrose administration should not be delayed if thiamine is not immediately available, even in alcoholic patients. Hypoglycemia should be corrected immediately, and thiamine should be administered as soon as possible.

**PERSISTENT ALTERED MENTAL STATUS**

If hypoglycemia is the sole cause of the altered mental status, restoration of euglycemia should lead to reversal of the neurologic symptoms within minutes. In the case of a seizure caused by hypoglycemia, the altered mentation may persist for a short period while the patient recovers from the postictal state. If a patient’s mental status remains altered for more than 15 minutes after return to euglycemia and there is no history of seizure, a secondary cause must be considered. The EP should return to the primary assessment and consider a broad
SECTION XVI  METABOLIC AND ENDOCRINE DISORDERS

differential diagnosis, including traumatic brain injury, anoxic brain injury, stroke, alcohol intoxication, opioid intoxication, central nervous system infection, liver failure, and renal failure. The coma cocktail should be given in full, if not administered earlier. Rapid-sequence intubation, computed tomography of the brain, and lumbar puncture may be indicated. If a lumbar puncture is performed, a low cerebrospinal fluid glucose value is not necessarily a sign of central nervous system infection because this value remains depressed for several hours after a low blood glucose concentration has been corrected.

DISPOSITION

DISCHARGE

Patients with hypoglycemia caused by a short-acting, easily reversed mechanism that is unlikely to recur may be considered for discharge (Box 163.1). A history of recurrent episodes of hypoglycemia may be an indication for hospital admission to adjust medications. When taken in massive doses, even short-acting insulin preparations can cause delayed, recurrent hypoglycemia because of altered pharmacokinetics. Renal failure also increases the half-lives of insulin preparations and can cause unexpected recurrent hypoglycemia.

For patients who are discharged from the ED, insulin doses should be reduced by 25% for the next 24 hours to reduce the risk for recurrent hypoglycemia. Patients should be educated about how to prevent hypoglycemia (see the “Patient Teaching Tips” box), and short-term follow-up with a primary care physician should be arranged.

Children with known idiopathic ketotic hypoglycemia can also be discharged home after the hypoglycemia has been reversed and an uneventful ED observation completed. Parents should be educated to avoid prolonged fasts in these children and to provide a bedtime snack. An initial diagnosis of idiopathic ketotic hypoglycemia should not be made in the ED; patients with symptoms consistent with this diagnosis require admission to exclude other potential causes of hypoglycemia.

BOX 163.1 Minimum Requirements for Discharge from the Emergency Department (ED) After a Hypoglycemic Episode

- Hypoglycemia fully and rapidly reversed without continuous infusion of dextrose
- Uneventful 4-hour ED observation with serial blood glucose measurements in the normal range and not trending downward
- Full meal eaten in the ED
- Cause of the hypoglycemia known and recurrence unlikely (i.e., short-acting insulin)
- Accidental hypoglycemia
- Isolated hypoglycemic episode (no other recent severe hypoglycemic events or frequent mild hypoglycemic events)
- No major concurrent illnesses
- Patient understands how to prevent future episodes
- Patient can accurately monitor blood glucose at home
- Responsible adult will monitor the patient for the next several hours
- Follow-up with a primary care physician arranged

OBSERVATION AND ADMISSION

Patients who do not meet the criteria outlined in Box 163.1 require admission or monitoring in an observation unit for at least 24 hours (Fig. 163.3). Because of the risk for recurrence, hospitalization is recommended for those with hypoglycemia caused by an oral hypoglycemic medication or an intermediate- or long-acting insulin. Hypoglycemia caused by sulfonylureas tends to be prolonged and severe, and intensive care unit admission may be necessary, especially if a continuous dextrose infusion is needed in addition to octreotide to maintain euglycemia. Experience with hypoglycemia caused by the meglitinides is limited, so these patients should be managed similar to those with sulfonylurea-induced hypoglycemia.

Patients with hypoglycemia that cannot be completely reversed in the ED, as well as patients with hypoglycemia caused by massive insulin overdoses, starvation, sepsis, liver failure, and adrenal insufficiency, should be admitted to the intensive care unit.

Psychiatry consultation is appropriate for cases of hypoglycemia involving suicide attempts, factitious disorder, and Munchausen by proxy.
**CHAPTER 163  HYPOGLYCEMIA**

**PATIENTS TREATED IN PREHOSPITAL SETTING**

Emergency medical service (EMS) personnel frequently treat hypoglycemia in the prehospital setting. After treatment and resolution of the symptoms, patients often refuse transport to the ED. Recent studies suggest that the risk for recurrent hypoglycemia is not different in patients transported to the ED and those released on the scene. Mechem et al. reported that 9% (9 of 103) of patients who initially refused transport to the ED contacted EMS again within 3 days because of recurrent hypoglycemia. Similarly, Lerner et al. found that 8% (3 of 38) of patients released by EMS experienced recurrent hypoglycemia in 24 to 48 hours. However, caution is advised because fatal cases of hypoglycemia have occurred following release by EMS. EMS personnel should encourage all patients with symptomatic hypoglycemia, especially those who do not meet the criteria listed in Box 163.1, to be transported to the ED.

**SPECIAL CONSIDERATION: ACCIDENTAL PEDIATRIC SULFONYLUREA INGESTION**

Children are particularly susceptible to the effects of sulfonylureas, and significant hypoglycemia can develop after the ingestion of a single tablet. Therefore, all pediatric patients with possible sulfonylurea ingestion should be evaluated in the ED. If hypoglycemia is present on arrival at the ED, treatment as outlined previously with dextrose, octreotide, oral feedings, and hospital admission is indicated. The optimal management of a child who ingested a sulfonylurea or is thought to have done so and who has a normal blood glucose concentration is debated in the literature, with recommendations varying from mandatory admission to 8-hour ED observation.

Two studies provide the best available data for directing the management of asymptomatic pediatric sulfonylurea ingestions. In a retrospective study of pediatric patients after sulfonylurea ingestion, Quadri et al. found that 27% (25 of 93) had a blood glucose concentration lower than 60 mg/dL 30 minutes to 16 hours after ingestion, with the mean time to development of hypoglycemia being 4.3 hours. All four patients in whom hypoglycemia developed after 8 hours had received a continuous dextrose infusion while euglycemic during the observation period. It is thought that the dextrose infusions delayed the onset of hypoglycemia in these patients.

In a prospective study of pediatric sulfonylurea ingestions, Spiller et al. found that hypoglycemia developed in 29% (54 of 185). In all but one of the hypoglycemic patients, low blood glucose developed within 8 hours of ingestion. The lone patient in whom hypoglycemia developed after 8 hours had been given a continuous dextrose infusion after a blood glucose measurement of 62 mg/dL at 3 hours.

In both studies, hypoglycemia developed more than 8 hours after ingestion only in patients who received prophylactic

**Fig. 163.3** Approach to a hypoglycemic adult in the emergency department. CHF, Congestive heart failure; H + P, history and physical examination; ICU, intensive care unit; OHA, oral hypoglycemic agent.
dextrose infusions. These infusions probably masked early hypoglycemia and potentially stimulated further pancreatic insulin secretion.

An 8-hour ED observation period for pediatric patients with asymptomatic sulfonylurea ingestion appears to be safe when the following protocol is used. An blood glucose measurement should be obtained immediately. Activated charcoal should be administered if the child is initially seen within 1 hour of ingestion and there is little risk for vomiting and aspiration. For an asymptomatic patient with a blood glucose concentration higher than 60 mg/dL, oral carbohydrates should be encouraged but no IV dextrose given. The blood glucose concentration should be checked every 30 to 60 minutes; a decrease in concentration to below 60 mg/dL is an indication for an IV dextrose bolus and hospital admission.

If the patient remains asymptomatic and blood glucose remains higher than 60 mg/dL for 8 hours after ingestion, the patient may be discharged with appropriate return precautions. However, hospitalization is advised if IV dextrose is administered at any time, if the ingestion involved extended-release glipizide (Glucotrol XL—a sulfonylurea with peak effects possibly delayed longer than 8 hours), or if the ingestion may have been intentional.

Sodium and Water Balance

Michael C. Wadman and Lance H. Hoffman

KEY POINTS

- Most signs and symptoms of clinically significant hyponatremia are related to an increase in cellular volume in the central nervous system and subsequent cerebral edema.
- Hyposmolar hypovolemic hyponatremia, the most common type of hyponatremia encountered in the emergency department, is seen in patients with severe total body water depletion in excess of sodium loss.
- Diagnostic criteria for the syndrome of inappropriate secretion of antidiuretic hormone (ADH) include hyposmolar hyponatremia, inappropriately concentrated urine, and exclusion of other causes of hyposmolar euvoletic hyponatremia such as hypothyroidism and adrenal insufficiency.
- Hypovolemic hyponatremia, the most common cause seen in the emergency department, results from severe total body water depletion.
- Patients with central diabetes insipidus produce dilute urine because of a decrease in ADH secretion from the hypothalamus; those with nephrogenic DI exhibit a decreased response to ADH at the renal tubule.
- Osmotic demyelination syndrome, the most serious complication of the treatment of hyponatremia, occurs when the administration of relatively hyperosmolar intravenous fluid causes intracellular water to rapidly diffuse out of central nervous system cells.
- The most serious complication of therapy for hyponatremia is the development of cerebral edema secondary to excessively rapid rehydration.

SCOPE

Water accounts for 60% of total body weight and is divided between two spaces or compartments: intracellular and extracellular. Osmotic equilibrium between the extracellular and intracellular spaces depends on free flow of water through a solute-impermeable/water-permeable membrane barrier. Water balance describes the normal state of equilibrium, with osmolality, the ratio of solute to free water, being constant between the two spaces when water diffuses freely across the membrane. The predominant solute of the extracellular space is sodium.

Various disease states may alter water balance and lead to abnormally high or low sodium levels that may result in significant disability or death from either the causative disease, the direct effects of the sodium concentration, or the ill effects of inappropriate treatment. The signs and symptoms range from subtle constitutional symptoms to seizure and coma. Suspicion for disorders of water balance depends on assessment of existing risk factors and the clinical information available at the time of arrival at the emergency department (ED).

Hyponatremia is diagnosed when the serum sodium level is lower than 135 mEq/L, but clinical signs and symptoms most often occur when sodium falls below 130. Hyponatremia most commonly occurs in the very young and the very old, with prevalence increasing with advancing age. Hyponatremia is observed in infants given tap water as a home remedy for gastroenteritis and in elderly patients with a poorly regulated thirst mechanism or an inability to procure fluids because of immobility (or both).1,2

Hypernatremia, a plasma sodium level higher than 145 mEq/L, most commonly results from inadequate water intake. In the very young, this situation usually occurs secondary to water loss exceeding intake, such as with diarrheal illness; in the geriatric population, hypernatremia may result from a poor sense of thirst or an inability to obtain adequate fluids because of physical or mental impairment. Hypernatremia is less common than hyponatremia, but it is associated with a far greater mortality rate of approximately 50%, primarily from the causative disease states in elderly patients and from the direct neurologic effects of the high sodium concentration in the very young.3

PATHOPHYSIOLOGY

Water balance is regulated through the homeostatic mechanisms of thirst and renal excretion. High serum osmolality is detected by hypothalamic osmoreceptors and leads to secretion of antidiuretic hormone (ADH) and stimulation of thirst. ADH regulates plasma osmolality by increasing free water absorption in the kidney. Low plasma osmolality results in suppression of ADH and the production of dilute urine.

Hypovolemia stimulates thirst, as well as the secretion of ADH and aldosterone. Aldosterone is synthesized in the
adrenal cortex and is secreted in response to hypovolemia via the renin-angiotensin-aldosterone axis. Aldosterone acts by increasing sodium absorption at the distal tubule, which leads to expansion of intravascular volume.

**HYPONATREMIA**

The low osmolality of the intravascular space and the relatively high osmolality of the intracellular space results in an osmotic gradient and diffusion of water into the cell. The resulting cellular edema is generally well tolerated by most tissues, except when it occurs in a confined space such as the central nervous system (CNS). The initial, rapid response to the increase in CNS cellular volume is diffusion of electrolytes and water out of the cell, which leads to a partial reduction in glial cell volume. Continuing hyponatremia over the next 48 to 72 hours generates slow diffusion of organic osmolytes, primarily large amino acids, out of the cell, thereby further reducing cell volume. Treatment of hyponatremia with intravenous fluid (IVF) may then lead to a state of relative hyperosmolality in the extracellular space with resultant diffusion of water out of the cell and continued reduction in cellular volume. This cycle creates the most serious treatment complication of hyponatremia: osmotic demyelination syndrome (otherwise known as central pontine myelinolysis).

**HYPERNATREMIA**

In hypernatremia, water diffuses out of the cell along the osmotic gradient, which results in loss of cellular volume. In the acute phase, electrolytes and water rapidly diffuse into the cell to partially restore cellular volume. With ongoing hypernatremia, slow redistribution of osmolytes occurs and water diffuses into the cell. With treatment, the relatively hyposmolar IVF leads to an osmotic gradient that promotes further diffusion of water into the cell. The size of the larger organic osmolytes prevents rapid diffusion out of the cell and results in the most serious treatment complication of hypernatremia: cerebral edema.

**CLINICAL PRESENTATION**

**HYPONATREMIA**

Most signs and symptoms of significant hyponatremia are related to an increase in CNS cellular volume and subsequent cerebral edema. The rapid compensatory mechanisms of the acute phase produce more obvious signs and symptoms, whereas the slow, adaptive phase of the chronic state results in minimal symptomatology.

The signs and symptoms of hyponatremia depend on both the rate of change and the absolute plasma sodium concentration. An acute fall in the serum sodium level below 120 always results in symptoms, whereas a more gradual decline to this level may go undetected.

Symptoms of hyponatremia include nausea, headache, and general malaise with sodium levels of 125 to 130 and lethargy, confusion, agitation, psychosis, and seizures as the sodium level falls to the range of 115 to 120; severe symptoms develop at 110 regardless of the rate of change. Severe CNS signs observed with hyponatremia include a decreased level of alertness, focal or generalized seizure activity, and signs of brainstem herniation such as unilateral dilated pupil, posturing, and respiratory arrest.

**HYPERNATREMIA**

The signs and symptoms of hypernatremia depend on age. Infants exhibit restlessness, tachypnea, characteristic high-pitched crying, alternating irritability and lethargy, and hypotonia. Elderly patients have nausea, weakness, altered mental status, agitation, irritability, lethargy, stupor, coma, and seizures. The severity of the CNS symptoms correlates with serum sodium levels.

**DIFFERENTIAL DIAGNOSIS AND CLASSIFICATIONS**

**HYPONATREMIA**

The differential diagnosis of hyponatremia begins with determination of serum osmolality (Fig. 164.1). Osmolality is measured by osmometry in the laboratory or is calculated according to the following formula:

\[
\text{Plasma osmolality} = \frac{2 \times \text{Na}^+ (\text{mEq/L})}{\left[18 + \frac{\text{glucose (mg/dL)}}{18}\right]} \left[ \frac{\text{BUN} (\text{mg/dL})}{2.8}\right]
\]

(BUN = blood urea nitrogen).

Depending on serum osmolality, the patient is classified as being either hyposmolar (plasma Osm < 275), isosmolar (275 to 290), or hyperosmolar (>290). In hyposmolar patients, clinical assessment of the patient’s volume status further differentiates hyponatremic patients as hypovolemic, euvolemic, or hypervolemic.

Hyposmolar hypovolemic hypernatremia, the most common type of hyponatremia encountered in the ED, is seen in patients with severe depletion of total body water (TBW) in excess of sodium loss. Urine osmolality and sodium determinations allow further narrowing of the differential diagnosis. Dilute urine (urine osmolality > 100 mOsm/kg) suggests polydipsia or beer potomania. In patients with urine osmolality greater than 100 mOsm/kg, urinary sodium levels lower than 20 mEq/L indicate an extrarenal source of the sodium and water loss. Extrarenal causes of hyponatremia include gastrointestinal problems such as vomiting or diarrhea and skin loss from severe burns. Urinary sodium levels higher than 20 mEq/L suggest a renal source of the sodium and water loss, such as sodium-losing nephropathy, hypaldosteronism, diuretic excess, or osmotic diuresis.

Hyposmolar euvolemic hypernatremia is most commonly associated with the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) (Box 164.1). ADH, or vasopressin, decreases free water excretion and results in inappropriately concentrated urine (urine osmolality >100 mOsm/kg) and a urine sodium concentration higher than 20 mEq/L. SIADH may result from various malignancies, pulmonary disorders, CNS diseases, and several drugs. Diagnostic criteria for SIADH include hyposmolar hypernatremia, inappropriately concentrated urine, and exclusion other causes of hyposmolar euvolemic hypernatremia such as hypothyroidism and adrenal insufficiency.

Hyposmolar hypervolemic hypernatremia occurs in patients retaining water in excess of sodium, which leads to an edematous state. Such patients with congestive heart failure, cirrhosis, or nephrotic syndrome retain sodium in response to a decreased effective intravascular volume, which results in a
The concentration of sodium in the plasma is affected by large molecules that increase the nonaqueous, sodium-free plasma fraction, which leads to a corresponding decrease in the concentration of sodium per unit volume of serum. The large molecules responsible for pseudohyponatremia are usually derived from a paraproteinemia (as with multiple myeloma) or from hyperlipidemia. Many newer laboratory methods for determination of sodium measure only the aqueous serum component, thereby eliminating the possibility of pseudohyponatremia.

Hyperosmolar hyponatremia commonly results from hyperglycemia. The high osmolality of the extracellular compartment secondary to high serum glucose drives water out of cells and dilutes the concentration of sodium. In the evaluation of a patient with hyperosmolar hyponatremia, a decrease in plasma sodium of 1.6 mEq/L for every 100-mg/dL increase in serum glucose provides an estimate of the degree of hyponatremia. A similar situation may also occur in patients receiving mannitol, sorbitol, or radiocontrast media.

**HYPERNATREMIA**

Hyperosmolar hyponatremia commonly results from hyperglycemia. The high osmolality of the extracellular compartment secondary to high serum glucose drives water out of cells and dilutes the concentration of sodium. In the evaluation of a patient with hyperosmolar hyponatremia, a decrease in plasma sodium of 1.6 mEq/L for every 100-mg/dL increase in serum glucose provides an estimate of the degree of hyponatremia. A similar situation may also occur in patients receiving mannitol, sorbitol, or radiocontrast media.
proximal to an intravenous (IV) line. When the results are in doubt, a new sample should be obtained to ensure accuracy.

Blood tests for the evaluation of sodium imbalance include plasma osmolality, sodium, potassium, BUN, glucose, and thyroid-stimulating hormone. Although most laboratories will report a plasma osmolality measured by osmometry, determination of sodium, glucose, and BUN allows calculation of osmolality. Plasma osmolality guides the initial classification of hyponatremia as true hyposmolar, hyperosmolar, or isosmolar. The diagnosis of true hyposmolar hyponatremia excludes paraproteinemia, hyperlipidemia, and hyperglycemia as causes of the low laboratory sodium levels. Normal thyroid-stimulating hormone and potassium levels exclude possible thyroid or adrenal causes of euvolemic hyposmolar hyponatremia.

Relevant urine studies include urine osmolality and urine sodium. High urine osmolality indicates the possibility of SIADH, whereas a low value suggests DI, excessive fluid intake, or hyperaldosteronism. Urine sodium levels obtained before the initiation of therapy provide diagnostic information regarding the source of the free water loss.

**TREATMENT**

**HYPONATREMIA**

Osmotic demyelination syndrome (ODS), the most serious complication of the treatment of hyponatremia, occurs when the administration of relatively hyperosmolar IVF causes intracellular water to rapidly diffuse out of CNS cells. Patients typically improve transiently after IVF administration, only to deteriorate a week after treatment. Signs and symptoms include altered mental status, dysarthria, vertigo, parkinsonism, pseudobulbar palsy, diffuse spastic hypertonia, quadripareisis, and coma. To minimize the risk for ODS, the absolute change in serum sodium over a 48-hour period must not exceed 8 mEq/L.
exceed 15 to 20 mEq/L. Additional risk factors for the development of ODS include alcoholism, malnutrition, and liver transplantation. 

In patients with severe neurologic symptoms (seizures, coma, or respiratory arrest) and laboratory-confirmed hypotonic hypovolemic hyponatremia, the likelihood of cerebral edema outweighs the potential risk for treatment-related ODS secondary to rapid correction of the hypotonic state. In this clinical situation, administration of hypertonic saline (HTS, 3%) is suggested for the first 2 to 4 hours or less if the patient’s condition improves with a maximum rate of sodium correction of 1.0 to 2.0 mEq/L/hr. Seizure risk usually declines with a serum sodium correction of approximately 5 mEq/L. Patients with acute hyponatremia for less than 48 hours may tolerate more rapid correction of the sodium concentration. Hyponatremic patients with less severe symptoms usually have a more chronic condition. The risk for ODS outweighs the benefits of rapid correction in this group, and the recommended rate of sodium correction is less than 0.5 mEq/L/hr. 

The following formula calculates the required volume of IVF needed to correct serum sodium to the desired level:

\[
\text{Required fluid volume (L)} = \frac{(Na_{\text{desired}} - Na_{\text{measured}})(TBW)}{Na_{\text{IVF}} - Na_{\text{measured}}}
\]

TBW in liters equals the patient’s mass in kilograms multiplied by a constant that depends on the patient’s gender and age (young men, 0.6; young women and elderly men, 0.5; elderly women, 0.4). See the “Facts and Formulas” box to determine the sodium content of 1 L of commonly used IVF.

For an 80-kg elderly man with seizures and a serum sodium level of 110 mEq/L, the goal of the emergency physician is to increase serum sodium to 115 mEq/L, with the probable effect being cessation of seizure activity. Using 3% saline, the required volume of IVF to attain a serum sodium level of 115 mEq/L is \((115 - 110)(80)(0.5)/(513 - 110)\), which equals 0.496 L (496 mL) of 3% saline to be infused over approximately a 2- to 3-hour period. 

Some authors do not endorse the use of formulas to guide the treatment of hyposmolar hyponatremic patients with seizures. Instead, they recommend an empiric IV bolus of 100 mL of 3% HTS, followed by up to two repeated doses if the seizures have not resolved, with the goal of increasing serum sodium 5 to 6 mEq/L in the first 1 to 2 hours of treatment. Monitoring of serum sodium after the second IV bolus and every 2 hours during HTS therapy is required to guide further therapy. HTS is discontinued once serum sodium levels have increased by 10 mEq/L in the first 5 hours or if the symptoms resolve. Further recommendations include avoidance of both overcorrection and an absolute increase exceeding 15 to 20 mEq/L in the first 48 hours of treatment. 

Most patients with euvolemic and hypervolemic hyponatremia require restriction of free water intake to 800 to 1000 mL/day. Patients with severe hyponatremia may need IVF to replace the total body sodium deficit.

**HYPERNATREMIA**

ED management of hypernatremia requires restoration of plasma volume. The choice of IVF depends on the clinical situation, but 0.9% normal saline (NS) is appropriate in the initial resuscitative treatment phase, with subsequent conversion to a hypotonic IVF such as 0.45% NS when euvoolemia is attained.

Once the serum sodium level is known, the goal rate of correction of the sodium concentration is 0.5 to 1.0 mEq/L/hr, not to exceed 10 mEq/L over a 24-hour period. One approach to correcting the water imbalance resulting in hypernatremia is to calculate the free water deficit and then replace the deficit over a 48-hour period under the assumption that plasma sodium increases approximately 5 mEq/L for each liter of water replaced. The free water deficit is calculated as follows:

\[
\text{Free water deficit (L)} = \frac{(Na_{\text{measured}} - Na_{\text{desired}})(TBW)}{Na_{\text{measured}}}
\]

In this formula, TBW equals patient mass (kg) multiplied by a constant that depends on the patient’s gender and age (young men, 0.6; young women and elderly men, 0.5; elderly women, 0.4). It is important to distinguish acute hypernatremia (<48 hours’ duration) from chronic hypernatremia (>48 hours’ duration) during ED management because this information has implications for the safe rate of correction of the patient’s free water deficit. Five percent dextrose in water (D5W) and 0.45% NS are the fluids most commonly used to replace a free water deficit. Refer to the “Facts and Formulas” box for the sodium content of 1 L of commonly used IVF. The free water deficit in patients with acute hypernatremia is usually replaced over a period of 2 days, whereas the free water deficit in patients with chronic hypernatremia is usually replaced over a period of 3 days to minimize risk for the development of cerebral edema.

For a 55-kg elderly woman with somnolence and dehydration of gradual onset, normal vital signs, a serum sodium level of 158 mEq/L, and a target sodium level of 140 mEq/L, her free water deficit in liters is \((158 - 140)(55)(0.4)/158\), or 2.506 L (2506 mL). Therefore, she will require approximately 2.5 L of D5W infused over a 3-day period to slowly correct her serum sodium to normal to minimize her risk for the development of cerebral edema.

Another correction method is to calculate the effect of 1 L of a given IVF on the patient’s sodium level by using the following formula and values described by Androgué and Madias (Box 164.2):

\[
1 \text{ L IVF} = \frac{Na_{\text{IVF}} - Na_{\text{measured}}}{TBW + 1}
\]
Calculation of the decrease in serum sodium for each liter of IVF administered permits close monitoring of the response to therapy. This method may facilitate changes during the course of therapy based on measured sodium levels.

The most serious complication of therapy for hypernatremia is the development of cerebral edema secondary to excessively rapid rehydration (see Box 164.2). In the chronic hypernatremic state, large organic osmolytes that slowly accumulated in CNS cells during the adaptive phase are unable to rapidly diffuse into the extracellular space when a relatively hypotonic fluid is administered.

Potassium

Megan Boysen Osborn

Potassium is the major intracellular cation and is closely regulated by the sodium-potassium adenosine triphosphatase (Na⁺,K⁺-ATPase) pump. Hypokalemia and hyperkalemia are electrolyte abnormalities common to both hospitalized and emergency department (ED) patients.1

Hypokalemia is observed more frequently than hyperkalemia and affects a broader range of patients; diuretic therapy accounts for as much as 80% of clinically significant cases seen in the ED.2 Hypokalemia is defined as a serum potassium level lower than 3.5 mEq/L. It is further classified as mild (3 to 3.5 mEq/L), moderate (2.5 to 2.9 mEq/L), and severe (<2.5 mEq/L). Hyperkalemia, a disorder that affects patients with underlying renal insufficiency almost exclusively,1 is defined as a potassium level higher than 5.0 mEq/L. Hyperkalemia is further classified as mild (5 to 6 mEq/L), moderate (6.1 to 7 mEq/L), and severe (>7 mEq/L).

Both disorders can result in cardiac dysfunction, arrhythmia, and death.

**PATHOPHYSIOLOGY**

Total body potassium (K⁺) is approximately 50 mEq/kg, or 3500 to 4000 mEq, in a normal-sized adult. For conversion purposes, 1 mEq of potassium is equivalent to 39.09 mg. Potassium is the major intracellular cation, and more than 98% of total body potassium is stored in the intracellular space. Intracellular fluid concentrations of potassium range from 150 to 160 mEq/L, with the highest amounts sequestered either in muscle (75%) or in bones and cartilage (8% to 10%).2

Extracellular potassium makes up less than 2% of total body stores, only two thirds of which is measurable in serum sampling. The normal range of plasma concentrations reported by most laboratory testing is 3.5 to 5 mEq/L; this small fraction is not reflective of total body potassium. Strict regulation of the ratio of intracellular to extracellular potassium (150 to 4 mEq/L) maintains a critical voltage gradient across cell membranes and plays a crucial role in establishing membrane potentials in cardiac and neuromuscular cells.1 The Na⁺,K⁺-ATPase transmembrane pump continuously maintains this gradient by actively transporting potassium into and sodium (Na⁺) out of cells1 (Fig. 165.1). Large changes in the intracellular potassium concentration have little effect on the ratio of intracellular to extracellular potassium. Conversely, even small changes in the extracellular concentration significantly affect this ratio, the transmembrane potential gradient, and the function of cardiac and neuromuscular tissue.1

All potassium disorders result from one of three disturbances: impaired potassium intake, impaired distribution of potassium between the intracellular and extracellular spaces, and impaired renal excretion of potassium (Fig. 165.2).

**KEY POINTS**

- Insulin enhances the activity of the sodium-potassium adenosine triphosphate pump, with a resultant decrease in extracellular potassium. Patients with diabetes mellitus are predisposed to hyperkalemia because of impaired insulin feedback and subsequently poor intracellular transfer of potassium.
- Asthmatic patients treated with bronchodilator therapy or epinephrine are predisposed to hypokalemia.
- Renal failure is responsible for the majority of cases of critical hyperkalemia seen in the emergency department.
- Calcium normalizes electrocardiographic manifestations of hyperkalemia within minutes of administration; however, the clinical effects are generally short-lived. Doses may need to be repeated within 30 minutes.
- Regular (short-acting) insulin administered as a 10-unit intravenous bolus will begin to lower serum potassium concentrations within 10 to 20 minutes, and the clinical effect lasts several hours. An ampule of 50% dextrose in water should be given concurrently to prevent hypoglycemia.
- Nebulized albuterol in 10- to 20-mg continuous treatments will transiently decrease serum potassium by 1 mEq/L over a 1- to 2-hour period.
- Definitive treatment of hyperkalemia is elimination of potassium. Hemodialysis is indicated for severe cases of hyperkalemia; when potassium-free dialysate is used, hemodialysis can reduce serum potassium by 1.5 mEq/hr.
Mild Hypokalemia (3 to 3.5 mEq/L)

Patients without significant comorbid conditions tolerate mild hypokalemia very well. Muscular symptoms are generally absent, although occasionally patients experience mild cramping or early muscle fatigue. Hypokalemia may affect smooth muscle function in the gastrointestinal tract with resultant constipation or abdominal cramping, or both. Cardiac and neurologic symptoms are absent.

Moderate Hypokalemia (2.5 to 2.9 mEq/L)

Muscular symptoms become more pronounced as the degree of hypokalemia worsens; the weakness is generalized, but proximal and lower extremity muscle groups are typically affected to a greater degree.2 Cardiac manifestations may include palpitations, non–life-threatening dysrhythmias (premature atrial contractions, premature ventricular contractions), and atrial fibrillation. Electrocardiographic (ECG) changes occur but do not correlate with the degree of hypokalemia (Box 165.2; Fig. 165.3).

Hypokalemia may precipitate or worsen encephalopathy in patients with severe liver disease. Potassium depletion increases renal production of ammonia, which readily crosses the blood-brain barrier in the setting of alkalosis.2 Hypokalemia also inhibits the release of insulin and may cause hyperglycemia in patients with preexisting glucose intolerance or non–insulin-dependent diabetes mellitus. The renal complications of moderate hypokalemia reflect vasopressin resistance to the tubular reabsorption of water; symptoms include nocturia, polydipsia, and polyuria.2

Severe Hypokalemia (<2.5 mEq/L)

Alcoholics have the greatest risk for severe hypokalemia. Musculoskeletal symptoms include pronounced fasciculations, tetany, and rhabdomyolysis. Myolysis may cause a transient release of intracellular potassium that can mask the inciting hypokalemic state. In rare cases, life-threatening ascending paralysis and loss of deep tendon reflexes can result in quadriplegia.2

Cardiac manifestations of severe hypokalemia worsen the previously mentioned ECG abnormalities. Of great

**CLINICAL PRESENTATION**

**Hypokalemia**

Approximately 20% of hospitalized patients are found to have subtherapeutic serum potassium levels.1 Despite this disease prevalence, most patients are asymptomatic, and only 5% of these patients have clinically significant hypokalemia.

In the outpatient setting, roughly 18% of patients have mild hypokalemia, which is generally asymptomatic. The vast majority of these cases (80%) are caused by potassium-wasting diuretic medications.2 Men and women are affected equally.

Symptoms of hypokalemia are determined by the degree of hypokalemia, the cell or organ type affected, and the general health of the patient. Healthy patients with gradual-onset hypokalemia are usually asymptomatic and have mild to moderate potassium depletion.

The effects of low serum potassium levels can range from vague myalgias to life-threatening paralysis or dysrhythmias. Because potassium is the major intracellular ion that maintains the charge gradient across cell membranes, any alteration in its concentration will have broad effects on muscle, cardiac, and gastrointestinal tissue. Skeletal muscle cells are the first to be affected, with patients experiencing cramping, fasciculations, and tetany. In patients with underlying ischemic heart disease or congestive heart failure, hypokalemia-induced dysrhythmia with mild to moderate potassium depletion is more likely to develop.

**Box 165.1** summarizes the clinical findings of hypokalemia.
BOX 165.1 Clinical Findings in Hypokalemia

Gastrointestinal
Ileus (nausea, vomiting, distention)

Vascular
Postural hypotension (decreased peripheral resistance and autonomic dysfunction)

Cardiac
Ventricular arrhythmias
Cardiac arrest
Bradyarrhythmias, tachycardia
Premature ventricular contractions, premature atrial complexes
Electrocardiographic abnormalities (see Box 165.2)
Enhanced digitalis toxicity

Respiratory
Hypoventilation, respiratory distress
Respiratory failure

Neurologic
Lethargy
Changes in mental status
Paralysis

Muscular
Cramping, restless legs syndrome
Decreased muscle strength, paralysis
Fasciculations, tetany
Decreased deep tendon reflexes
Rhabdomyolysis

Renal
Nephrogenic diabetes insipidus
Metabolic alkalosis
Impaired urinary concentrating ability (polyuria)
Increased ammonia production and hydrogen ion excretion
Hypokalemic nephropathy (interstitial renal disease)

Other
Cushingoid appearance (edema)
Inhibition of insulin release
Aldosterone inhibition
Negative nitrogen balance

BOX 165.2 Electrocardiographic Abnormalities in Mild to Moderate Hypokalemia

Low, flattened, or inverted T waves
Potassium concentration usually less than 3.5 mEq/L
Decreased or depressed ST segment
Increased PR interval
Increased QRS duration
U waves
- Taller than T waves
- Seen in septal leads (V2, V3)
Prominent R wave
Atrial or ventricular arrhythmias

Fig. 165.3 Electrocardiographic findings in hypokalemia. A, Normal. B, Mild T-wave flattening (the earliest change). C, U wave associated with T-wave flattening. D, Slight ST depression and a “pseudo-P pulmonale” pattern. E, ST depression is more noticeable, and the U wave increases in amplitude. F, The U wave overcomes the T wave—“QU” prolongation.

Mild Hyperkalemia (5 to 6 mEq/L)
Mild hyperkalemia is generally asymptomatic. Patients with underlying cardiac disease occasionally report palpitations or other well-tolerated disturbances in rhythm.

Moderate Hyperkalemia (6.1 to 7 mEq/L)
Patients with moderate hyperkalemia may exhibit ECG abnormalities, including peaked T waves and prolongation of the PR interval and QRS complex (Figs. 165.4 to 165.7; Box 165.3).

Neuromuscular symptoms similar to those seen with hypokalemia can occur. Muscle cramps and weakness are the most commonly reported complaints.

come is the development of potentially life-threatening ventricular arrhythmias in patients with preexisting cardiac disease. Ventricular ectopy ranges from premature ventricular contractions to couplets, bigeminy, trigeminy, and episodes of ventricular tachycardia, torsades de pointes, and ventricular fibrillation. In the setting of myocardial infarction or digitalis toxicity, hypokalemia-induced ventricular dysrhythmias are directly proportional to the degree of potassium depletion.2

HYPERKALEMIA
Hyperkalemia is often asymptomatic and discovered only on routine laboratory screening. When symptoms do occur, conduction abnormalities at the cellular level promote cardiac and
Severe Hyperkalemia (>7 mEq/L)

Progressively worsening hyperkalemia can result in significant conduction abnormalities, heart block, potentially life-threatening arrhythmias, and asystole. Symptoms such as palpitations, syncope, chest pain, and dyspnea (from left-sided heart failure) may be present. Ascending paralysis and tetany may result.

**DIAGNOSTIC TESTING**

HYPOKALEMIA

Historical elements that may mandate measurement of serum potassium include potential causes of inadequate intake (malnutrition, alcoholism) and excessive wasting (diarrhea, vomiting, polyuria). Long-standing use of diuretics, β2-agonists, or laxatives should also prompt potassium screening.

In the ED, evaluation should focus on identification of hypokalemia by laboratory testing, classification of disease severity, correlation with findings on physical examination,

**Severe Hyperkalemia (>7 mEq/L)**

Progressively worsening hyperkalemia can result in significant conduction abnormalities, heart block, potentially life-threatening arrhythmias, and asystole. Symptoms such as palpitations, syncope, chest pain, and dyspnea (from left-sided heart failure) may be present. Ascending paralysis and tetany may result.

**DIAGNOSTIC TESTING**

HYPOKALEMIA

Historical elements that may mandate measurement of serum potassium include potential causes of inadequate intake (malnutrition, alcoholism) and excessive wasting (diarrhea, vomiting, polyuria). Long-standing use of diuretics, β2-agonists, or laxatives should also prompt potassium screening.

In the ED, evaluation should focus on identification of hypokalemia by laboratory testing, classification of disease severity, correlation with findings on physical examination,
and correction or stabilization of potentially life-threatening conditions.

If hypokalemia is identified, screening for hypomagnesemia and hypophosphatemia is necessary; these coexistent entities are difficult to distinguish from hypokalemia by physical examination alone. Urine pH higher than 6 suggests type I renal tubular acidosis; urine electrolytes and venous blood gas analysis should be obtained to search for a corresponding normal–anion gap metabolic acidosis.

If the patient is taking digoxin, a serum digoxin level is indicated; hypokalemia potentiates digitalis toxicity and increases the likelihood of cardiac dysrhythmias. Additional laboratory testing and imaging can be performed later in the inpatient or outpatient setting.

**HYPERKALEMIA**

Patients with hyperkalemia be asymptomatic or have life-threatening cardiovascular disturbances. Historical features that should raise suspicion for hyperkalemia include known acute or chronic renal insufficiency, potassium supplementation, and ECG changes following an incomplete hemodialysis session. End-stage renal dialysis patients who have missed a scheduled dialysis session should be placed on a cardiac monitor and immediately be screened for ECG abnormalities and electrolyte disturbances.

The first sign of hyperkalemia may be abnormal ECG findings on arrival at the ED. If hyperkalemia is suspected in an asymptomatic renal patient with abnormal ECG findings, a complete serum chemistry panel should be obtained, as well

---

**Fig. 165.6**  Patient with severe hyperkalemia on arrival at the emergency department (K⁺ = 8.3 mmol/L).

**Fig. 165.7**  Patient during treatment of severe hyperkalemia, now with mild to moderate hyperkalemia (K⁺ = 6.3 mmol/L).
as a whole blood potassium level measured by venous blood gas analysis. Arterial or venous blood gas sampling is generally the most efficient method of obtaining an accurate measurement of the potassium concentration.

Additional laboratory tests useful in the ED evaluation of hyperkalemia include serum calcium, creatinine, digoxin, and blood pH. Other testing can be deferred to the inpatient setting.

TREATMENT (Table 165.1)

**HYPOKALEMIA**

**Patients with Cardiovascular Disease**

Optimal goals for serum potassium repletion are predicated on the underlying pathology. Patients with a history of congestive heart failure, coronary artery disease, or dysrhythmias and hypertensive patients being treated with diuretic medications should have a serum potassium level of at least 4 mEq/L. These patients require oral supplementation for even mild, asymptomatic hypokalemia with potassium chloride tablets (20 to 40 mEq daily). If the patient is taking a potassium-sparing diuretic, the dose should be decreased.

**Asymptomatic Mild Hypokalemia**

Healthy patients with asymptomatic, mild hypokalemia (3 to 3.5 mEq/L) do not require pharmacologic potassium supplementation. Treatment should be focused on minimizing further potassium loss and increasing oral intake. Patients should be encouraged to eat a diet rich in potassium (Box 165.4). Potassium-wasting diuretics should be decreased or eliminated, as blood pressure allows. Use of substances that contain glycyrrhizic acid (e.g., licorice, chewing tobacco, laxatives) should be avoided.

**Symptomatic Mild and Moderate Hypokalemia**

Potassium supplementation is required for patients with symptomatic mild or moderate (<3 mEq/L) hypokalemia. Potassium supplements are available in several forms: potassium chloride, potassium phosphate, potassium citrate, potassium acetate, potassium gluconate, and potassium bicarbonate. Potassium chloride is the preferred formulation for most ED cases of hypokalemia. Potassium phosphate may be beneficial in certain cases of diabetic ketoacidosis. Oral potassium supplements are available as tablets, powder, or elixir.

Dosing ranges from 20 to 80 mEq/day; doses greater than 40 mEq should be divided and given either two or three times per day. Oral therapy should be monitored daily because serum potassium levels will rise within 48 to 72 hours. Healthy patients who require daily oral supplementation can be discharged from the ED safely if repeated serum potassium measurements can be monitored by the primary care physician for 1 to 2 days. Patients who are elderly, have significant comorbid conditions, or have poor access to follow-up should be admitted to the hospital for a 24-hour observation period.

Magnesium deficiency should be suspected in patients who fail to respond to oral potassium therapy within 96 hours. Magnesium promotes activity of the Na⁺,K⁺-ATPase pump, which will replenish intracellular fluid concentrations in the first days of potassium supplementation.

**Severe Hypokalemia**

Intravenous (IV) potassium replacement is indicated for patients with severe hypokalemia (<2.5 mEq/L) or moderate hypokalemia accompanied by cardiac arrhythmias, familial periodic paralysis, or severe myopathy. Replacement consists of 100 mEq of potassium chloride in 1 L of normal saline (or 5% dextrose in water [D₅W]) infused
at a rate of 100 to 200 mL/hr (10 to 20 mEq/hr). If the patient has any form of heart block or renal insufficiency, the initial infusion rate should be reduced to 50 mL/hr (5 mEq/hr).

In rare instances of extreme hypokalemia or life-threatening clinical findings, potassium may be infused at a rate of 40 to 60 mEq/hr (400 to 600 mEq/L of normal saline at 100 mL/hr) for a short period (10 to 20 minutes). Therapy should be monitored with great caution. Serum potassium levels should be rechecked after every 40 to 60 mL infused.

IV potassium supplementation can cause excruciating phlebitis and cardiac arrest if directly injected into a vessel—potassium should never be administered as an IV push. Peripheral IV lines can be used for rates of 10 to 20 mEq/hr or less. In cases of moderate hypokalemia, potassium infusions should remain at 10 mEq/hr. To minimize the risk for phlebitis, a central line is necessary for infusion rates greater than 20 mEq/hr (see earlier indications). There is a theoretic concern for cardiac arrest when potassium is administered via central venous access—splitting the potassium infusion rate over two peripheral lines may be preferable. In general, patients receiving IV potassium supplementation require telemetry monitoring and frequent repeated potassium measurements (up to every 1 to 3 hours after the initial infusion begins). Significant potassium depletion may take days to correct. As serum potassium levels approach 3.5 mEq/L, patients should be converted to oral therapy if possible. IV potassium supplementation should be discontinued if any ECG signs of hyperkalemia are noted or if a single potassium measurement is higher than 3.5 mEq/L.

Unstable ventricular arrhythmias resulting from severe hypokalemia should be managed according to standard practice guidelines. Severe neuromuscular manifestations may endanger adequate respiratory effort and therefore mandate aggressive airway stabilization. Any volume depletion should be corrected, and coexisting medical conditions that may exacerbate the effects of hypokalemia should be addressed.

HYPERKALEMIA

Management of hyperkalemia focuses on three goals of care: cardiac stabilization, transcellular shift of potassium from extracellular fluid to intracellular fluid, and elimination of excess potassium (Table 165.2). Only potassium excretion is a definitive treatment step—other actions serve to temporarily stabilize the cell membrane in an effort to prevent hemodynamic collapse.

CARDIAC STABILIZATION: CALCIUM

IV calcium rapidly antagonizes the adverse effects of moderate to severe hyperkalemia on cell membrane potential in cardiac myocytes. Calcium can be administered as IV calcium chloride or calcium gluconate, even in patients who are normokalemic. IV preparations of calcium chloride contain three times more calcium per ampule than do calcium gluconate formulations. Calcium chloride is more likely than calcium gluconate to cause tissue necrosis if it extravasates. Calcium normalizes ECG manifestations of hyperkalemia.

within minutes of administration; however, the clinical effects are generally short-lived. Doses may need to be repeated within 30 minutes or if no effects are observed within 5 to 10 minutes of the initial dose. Calcium should be administered to patients with hyperkalemia-induced ECG changes, and caution should be exercised in patients taking digoxin.

**Transcellular Shift: Insulin and Albuterol**
Potassium can be temporarily shifted from the extracellular to the intracellular compartment through stimulation of the Na⁺,K⁺-ATPase pump by insulin or a β₂-agonist such as albuterol. Although either of these agents can temporize moderate hyperkalemia when given alone, studies suggest that combination therapy with both agents may be more efficacious.

Insulin forces a transcellular shift of potassium into liver and muscle cells. Regular (short-acting) insulin administered as a 10-unit IV bolus will begin to lower serum potassium concentrations within 10 to 20 minutes, and the clinical effect lasts several hours. An ampule of D₅₀W should be given concurrently to prevent hypoglycemia; patients who are already hyperglycemic (>250 mg/dL) do not require supplemental dextrose. Blood glucose should be rechecked 1 hour after insulin administration because hypoglycemia may develop despite initial supplementation with dextrose.

Albuterol is the most readily available β₂-agonist used to treat hyperkalemia in the ED. Nebulized albuterol in 10- to 20-mg continuous treatments will decrease serum potassium by 1 mEq/L over a 1- to 2-hour period. Though not approved for use in the United States, IV administration of albuterol shifts potassium into the intracellular fluid compartment even more rapidly. Once routinely used for treatment of hyperkalemia, the use of sodium bicarbonate has been challenged. Recent studies have demonstrated that sodium bicarbonate may only enhance urinary elimination of potassium and does not function at a cellular level. It may have especially a deleterious effect on anuric patients and worsen the degree of intracellular acidosis.

**Elimination: Resin Exchange (Kayexalate) and Dialysis**
Definitive treatment of hyperkalemia is elimination of potassium. For patients with renal insufficiency, resin exchange (Kayexalate) and dialysis are the mainstays of therapy. Potassium-wasting diuretics (thiazides, loop diuretics) may be taken by patients with normal renal function and mild asymptomatic hyperkalemia. Sodium bicarbonate infusion may also promote renal secretion of potassium but is no longer considered a first-line agent in the treatment of hyperkalemia.

Sodium polystyrene sulfonate (Kayexalate) is an inert resin that exchanges sodium for potassium in the intestinal tract. One gram of Kayexalate removes approximately 0.5 to 1 mEq of potassium in exchange for 2 to 3 mEq of sodium. The usual dose of Kayexalate is 30 to 60 g given orally or rectally. Oral Kayexalate begins to reduce total body potassium within several hours of administration, and the clinical effect lasts 4 to 6 hours. Rectal Kayexalate has a shorter time to onset than the oral formulation but is less efficacious.

Emerging literature questions the efficacy and safety of Kayexalate. Although Kayexalate reliably decreases serum potassium when administered over a period of several days, recent literature reviews suggest that the acute effects of the resin may not be as significant as once thought. Colonic necrosis, ischemic colitis, colonic bleeding, and perforation have been reported when Kayexalate is combined with 70% sorbitol. Kayexalate is often premixed with 33% sorbitol to prevent resin-induced constipation, and there is little evidence to suggest that Kayexalate with 33% sorbitol causes significant colonic pathology at standard doses. Very rare instances of colonic injury have been observed when 33% sorbitol is coadministered with Kayexalate as an enema to patients after recent colon surgery. High-dose Kayexalate precipitates pulmonary edema by increasing extracellular sodium in fluid-overloaded patients.

Hemodialysis is the most rapid method of potassium elimination in patients with persistent, symptomatic, or severe hyperkalemia. If a potassium-free dialysate is used, serum potassium may decrease as much as 1.5 mEq/L/hr. Stable patients may be transferred to an inpatient hemodialysis unit for therapy under strict cardiac monitoring. Patients with ECG abnormalities, hypotension, significant volume overload, or respiratory distress should undergo dialysis in the ED or intensive care unit. Cell membrane stabilization with IV calcium, IV insulin or glucose, and inhalational albuterol is necessary to prevent arrhythmia while awaiting emergency hemodialysis.

Calcium, Magnesium, and Phosphorus

Katrina A. Leone

Calcium

Approximately 99% of total body calcium is located in bone as the calcium phosphate salt hydroxyapatite. Of the remaining total body calcium, 45% is bound to albumin; 10% is complexed with circulating ions such as bicarbonate, phosphate, citrate, or sulfate; and the remaining 45% is found in the free, ionized form. The normal range for serum calcium is 8.5 to 10.5 mg/dL, with some variability among different laboratories. The normal range of ionized (unbound) calcium is 4.5 to 5.6 mg/dL, but this is often reported in the international units (SI units) of mmol/L, with the normal range being 1.1 to 1.4 mmol/L. This ionized fraction is responsible for the physiologic actions of calcium and is not dependent on albumin levels. The total serum calcium level can be corrected for the amount of serum albumin (see the “Facts and Formulas” box), but such correction can be unreliable, so an ionized calcium level should be obtained whenever true hypercalcemia or hypocalcemia is a concern.

The plasma concentration of calcium is tightly maintained within the normal range by a feedback-regulated endocrine system that balances interactions among the small intestines, kidneys, bones, parathyroid glands, thyroid gland, and bloodstream. The key regulatory molecules in this system include calcium, phosphorus, parathyroid hormone (PTH), and 1,25-dihydroxyvitamin D (calcitriol)(Fig. 166.1).

HYPERCALCEMIA

Epidemiology

Hypercalcemia is defined as a total serum calcium level greater than 10.5 mg/dL and is often divided into categories to describe the severity of symptoms as mild (10.5 to 11.9 mg/dL), moderate (12 to 13.9 mg/dL), and severe (>14 mg/dL). The prevalence of hypercalcemia is approximately 0.5% to 3% in hospitalized adults. Hyperparathyroidism is the most common cause of hypercalcemia, and the incidence of primary hyperparathyroidism is approximately 21 cases per 100,000 person-years.

The paraneoplastic syndrome hypercalcemia of malignancy is the second most common cause of hypercalcemia and occurs in approximately 10% to 30% of patients with cancer. Multiple myeloma and lung, breast, and prostate malignancies are most often associated with this disorder. It is typically seen in the end stages of disease and indicates a poor prognosis.

KEY POINTS

- Regulation of calcium, magnesium, and phosphorus is interrelated, and abnormalities in one are highly correlated with other electrolyte abnormalities.
- Severely depressed mental status and precipitation of arrhythmias are the most dangerous consequences of severe abnormalities in calcium, magnesium, or phosphorus.
- Proper correction of electrolyte deficiencies requires knowledge of the various oral and intravenous electrolyte preparations available.
PATHOPHYSIOLOGY

Under normal conditions, excess calcium is excreted together with sodium in the proximal tubules of the kidneys. With hypercalcemia, dehydration caused by vomiting, poor oral intake, and osmotic diuresis results in reabsorption of sodium instead of excretion. This concurrent calcium reabsorption exacerbates the underlying hypercalcemia. PTH regulates the renal excretion of calcium. The excess production of PTH in primary hyperparathyroidism results in inappropriate calcium reabsorption. Causes of primary hyperparathyroidism include solitary adenomas (most common), ectopic adenomas in the mediastinum, diffuse hyperplasia of one or more parathyroid glands, and parathyroid carcinoma. These parathyroid abnormalities may be independent or a component of the multiple endocrine neoplasia syndromes (MEN 1 or 2a).

Bone acts as a pool of calcium that is regulated by the balance between osteoblast and osteoclast activity. Calcium is released from bone by relative overactivation of osteoclasts and is enhanced by PTH. Prolonged hyperparathyroidism results in osteopenia.

The small intestines are the location of calcium absorption from the diet. Absorption is facilitated by vitamin D. Inactive forms of vitamin D$_3$ are synthesized in the skin in response to exposure to sunlight; vitamin D$_2$ is ingested from a normal diet. Vitamins D$_2$ and D$_3$ are subsequently converted into the active form 1,25-dihydroxyvitamin D (calcitriol) by enzymatic hydroxylation first in the liver and then in the kidney. Calcitriol acts on villi of the small intestines to augment absorption of calcium and phosphorus. Calcitriol also acts on bone to increase osteoclast activity. Excessive ingestion of vitamin D supplements is a rare cause of hypercalcemia. A serum 25-hydroxyvitamin D concentration greater than 125 nmol/L (50 ng/mL) is considered to be excessive, and greater than 500 nmol/L (200 ng/mL) is potentially toxic.

In the paraneoplastic syndrome hypercalcemia of malignancy, the majority of cases of hypercalcemia arise from tumor secretion of parathyroid hormone–related protein (PTHrP), a PTH homologue that acts on tissues like PTH does. Osteolytic bone metastases and ectopic tumor production of calcitriol and PTH cause the remaining cases of hypercalcemia of malignancy.

Milk-alkali syndrome is the third most common cause of hypercalcemia severe enough to result in hospitalization. The clinical definition of milk-alkali syndrome is hypercalcemia, alkalosis, and renal failure in a patient ingesting excessive amounts of calcium and an alkali. Diagnosis is based on the patient history when other causes of hypercalcemia are excluded. Over-the-counter calcium carbonate supplements are commonly used for dyspepsia and prevention of
osteoporosis and are currently the most frequent cause of milk-alkali syndrome. Historically, ingestion of milk and sodium bicarbonate for the treatment of peptic ulcer disease was the most common cause of milk-alkali syndrome, but this medication regimen went out of favor with the availability of H₂ receptor antagonists and proton pump inhibitors. Serum PTH is low in these patients, indicative of no concurrent hyperparathyroidism.

Several medications rarely cause hypercalcemia. Thiazide diuretics, lithium, and the vitamin A derivatives all-trans-retinoic acid and cis-retinoic acid have been implicated. Some systemic illnesses also have the potential to cause hypercalcemia, including the granulomatous diseases sarcoidosis, leprosy, coccidiomycosis, histoplasmosis, and tuberculosis. The mechanism of hypercalcemia in these conditions is thought to be production of calcitriol by macrophages within granulomas. Additionally, rare inherited disorders such as familial hypocalciuric hypercalcemia cause hypercalcemia.

**PRESENTING SIGNS AND SYMPTOMS**

Patients often become symptomatic from hypercalcemia at levels near 12 mg/dL, and nearly all patients with levels higher than 14 mg/dL will be symptomatic. Hypercalcemia affects a broad array of organ systems (Box 166.1).

Neurologic symptoms progress with increasing serum levels of calcium and range from mild cognitive impairment and depression to drowsiness, altered mental status, delirium, and obtundation.

Gastrointestinal symptoms include anorexia, constipation, nausea, vomiting, and paralytic ileus. Pancreatitis secondary to hypercalcemia is a well-described clinical phenomenon, but the exact mechanism of the development of this condition is still unclear. There is also an association between hypercalcemia and the development of peptic ulcer disease, in addition to a link between milk-alkali syndrome and antacid use in the treatment of this condition.

A common renal manifestation of hypercalcemia is osmotic diuresis manifested as polyuria and excessive thirst. Nephrolithiasis and nephrocalcinosis are hallmarks of hypercalcemia. In patients with primary hyperparathyroidism, up to 20% have a history of symptomatic nephrolithiasis. Case series of patients with kidney stones have demonstrated a 2% to 8% incidence of primary hyperparathyroidism. It is thought that excessive calciuria combined with dehydration and decreased urine output leads to stone formation.

Cardiac manifestations of hypercalcemia are generally manifested as asymptomatic electrocardiographic (ECG) changes. Shortening of the QT interval (QTc <0.4 msec) is common, and ST elevations that may mimic acute myocardial infarction have been reported (Fig. 166.2). Symptomatic cardiac manifestations are rare and generally limited to bradydysrhythmias.

Musculoskeletal symptoms of hypercalcemia include muscle weakness, bone pain, and osteopenia.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The serum calcium level is generally reported when a basic or comprehensive metabolic panel is ordered. Special consideration of hypercalcemia should be included in the evaluation of vague chief complaints such as fatigue, weakness, nausea and vomiting, abdominal pain, and altered mental status.

Discovery of significant hypercalcemia on laboratory testing should prompt a directed history for idiopathic causes of hypercalcemia, including ingestion of calcium or vitamin D supplements and use of thiazide diuretics or lithium. Evaluation for hyperparathyroidism, granulomatous diseases, and neoplasms should follow if a cause is not discovered on the history.

**TREATMENT**

Initial therapy for hypercalcemia includes correction of dehydration and facilitation of renal excretion of calcium through volume reexpansion with normal saline at a rate of 200 to 500 mL/hr. Patients with severe hypercalcemia may require several liters of fluid resuscitation. For example, in a case series of patients with severe hyperparathyroid crisis requiring parathyroidectomy, a mean of 16 ± 6 L of isotonic fluid was administered over a period of several days before surgery.

Loop diuretics may be used to facilitate forced calcium excretion in urine. Evidence for the effectiveness of loop diuretics is poor, and they should be used only after normovolemia has been achieved.

An additional therapy that has been studied most extensively in patients with hypercalcemia of malignancy is the use of bisphosphonates. These medications act on osteoclasts and limit release of calcium from bone. Their maximum calcium-lowering effects do not occur until several days after administration and can last for several weeks to months. Side effects of the bisphosphonates include hypophosphatemia, hypomagnesemia, osteonecrosis of the jaw, and postadministration acute phase reactions (fever, arthralgias, fatigue, malaise, myalgias). Table 166.1 summarizes the dosing regimens for available bisphosphonates.

A treatment of hypercalcemia that is immediately effective in lowering serum calcium is calcitonin. Calcitonin inhibits urinary reabsorption of calcium and osteoclast maturation. The most commonly available form of this medication is...
salmon calcitonin administered at 4 to 8 U/kg subcutaneously every 8 to 12 hours. Lowering of the serum calcium level can occur as quickly as 2 hours after administration, but the effects are generally modest (lowering calcium by up to 3.8 mg/dL) and short-lived. Tachyphylaxis to this treatment occurs within 2 days. Side effects of salmon calcitonin include flushing, nausea, vomiting, and abdominal cramps.

Glucocorticoids inhibit conversion of 25-hydroxyvitamin D to calcitriol, which causes a decrease in intestinal absorption of calcium and an increase in renal calcium excretion. Efficacy in lowering serum calcium has been demonstrated only in the treatment of certain types of lymphoma that secrete calcitriol, vitamin D intoxication, and the granulomatous diseases. Additionally, administration of glucocorticoids may delay tachyphylaxis to calcitonin, so they are often used in conjunction with salmon calcitonin. A common regimen for the treatment of hypercalcemia is hydrocortisone, 200 to 300 mg/day intravenously for 3 to 5 days.

An older medication for the treatment of hypercalcemia that has primarily been supplanted by use of the bisphosphonates is gallium nitrate. Gallium nitrate acts to lower serum calcium by inhibition of osteoclast activity. It is also thought to inhibit PTHrP. The typical dose is 200 mg/m²/day of gallium nitrate for 5 days by continuous infusion. The need for several days of continuous infusion is a significant drawback to the use of this medication. Because of risk for nephrotoxicity, gallium nitrate is generally indicated only when bisphosphonates are contraindicated or in refractory cases of hypercalcemia of malignancy when tumors exhibit a high level of PTHrP secretion.

An important step in the treatment of all causes of hypercalcemia is discontinuation of vitamin D and calcium-containing products. In the setting of milk-alkali syndrome, discontinuation of supplements and fluid resuscitation are often the only treatments required. Hemodialysis may be indicated for patients with severe hypercalcemia complicated by renal failure or for cases refractory to other therapies.

Follow-up, Next Steps in Care, and Patient Education

Hospital admission is indicated for patients with symptomatic hypercalcemia, especially in the setting of altered mental status, dehydration, or acute renal failure. Definitive treatment of any underlying diseases causing hypercalcemia should be...
undertaken, as clinically appropriate. This may include parathyroidectomy for primary hyperparathyroidism or initiation of therapy for malignancy. Patients should be educated about the proper use of dietary supplements or antacids containing calcium and vitamin D (Table 166.2).

## HYPOCALCEMIA

### EPIDEMIOLOGY

Hypocalcemia is defined as a serum calcium level lower than 8.5 mg/dL, although symptoms of hypocalcemia typically do not occur until serum calcium is below 7.0 to 7.5 mg/dL or ionized calcium is below 2.8 mg/dL (0.7 mmol/L). The incidence of hypocalcemia has not been well quantified.

### PATHOPHYSIOLOGY

The most common cause of hypocalcemia is hypoparathyroidism, which is defined as inadequate release of PTH from the parathyroid glands. Inappropriate release of PTH results in poor calcium absorption from the gastrointestinal tract, excessive excretion of calcium in urine, and sequestration in bone.

The most common cause of hypoparathyroidism is neck surgery, specifically parathyroidectomy, followed by thyroidectomy and then other neck surgeries. Autoimmune destruction of the parathyroid glands also causes hypoparathyroidism. Antiparathyroid antibodies are found in more than 30% of patients with isolated hypoparathyroidism and in more than 40% of patients with hypoparathyroidism accompanied by other autoimmune diseases. Infiltration of the parathyroids as a result of sarcoidosis, Wilson disease, hemochromatosis, or amyloidosis is a rare cause of hypoparathyroidism.

Pseudohypoparathyroidism is defined as a blunted renal response to PTH and is manifested similar to hypoparathyroidism as low serum calcium and elevated phosphorus levels; PTH in this setting is normal or elevated. Several genetic pseudohypoparathyroid syndromes are associated with hypocalcemia, as well as abnormal skeletal development, dysmorphic features, and abnormal development.

Vitamin D deficiency (rickets) is rarely symptomatic in adults unless hypocalcemia develops. The majority of patients with vitamin D deficiency have osteopenia with potential for the development of osteoporosis and pathologic fractures. It is most common in elderly, hospitalized, or institutionalized persons. These patients have impaired skin production of vitamin D in response to sun exposure because of aging, a low amount of sun exposure, or dietary deficiency. Individuals with darker skin that is highly pigmented by melanin are at higher risk than lighter-skinned individuals for vitamin D deficiency secondary to relative underproduction of vitamin D in response to sun exposure. Measurement of 25-hydroxyvitamin D is considered the best measure of body vitamin D stores. Serum levels of 25-hydroxyvitamin D below 30 to 50 nmol/L (<12 to 20 ng/mL) are considered deficient.

Pancreatitis causes hypocalcemia when peripancreatic fat combines with extracellular calcium to form insoluble salts. This processes is called saponification. Other causes of hypocalcemia include sepsis, critical illness, chronic renal failure, and massive transfusion of blood anticoagulated with citrate.

DiGeorge syndrome is a rare genetic disorder caused by deletion of a portion of chromosome 22 at the location 22q11.2. Hypocalcemia is a common component of this syndrome because of parathyroid agenesis or dysgenesis. Children with this disorder may exhibit hypocalcemia shortly after birth, and many require lifelong treatment for prevention of hypocalcemia.

The electrolyte abnormalities hyperphosphatemia and hypomagnesemia also cause hypocalcemia. Drugs and toxins implicated as causes of hypocalcemia include bisphosphonates, cisplatin, ketoconazole, phenytoin, phenobarbital, proton pump inhibitors, H2 receptor antagonists, aminoglycosides, phosphate-based enemas or laxatives, and exposure to hydrofluoric acid.

### PRESENTING SIGNS AND SYMPTOMS

The primary symptoms of hypocalcemia are manifestations of calcium’s critical role in the contraction and relaxation of skeletal and smooth muscle, as well as neurotransmission (Box 166.2). Neurologic symptoms often include both sensory and motor complaints. Sensory findings include perioral and extremity paresthesias. The most common motor abnormalities are neuromuscular irritability, including muscle cramps, hyperreflexia, carpal-pedal spasms, tetany, and seizures. Smooth muscle manifestations of hypocalcemia include

94% of hypocalcemic patients having a positive sign. The Trousseau sign is defined as carpal and digit spasm elicited by occluding the brachial artery with a sphygmomanometer inflated to 20 to 30 mm Hg above systolic blood pressure for 3 minutes (Fig. 166.3).

Neuropsychiatric manifestations of hypocalcemia include irritability, depression, anxiety, confusion, hallucinations, psychosis, and extrapyramidal symptoms (tremor, akathisia, slurred speech, dystonia, muscle rigidity, bradyphobia, and bradykinesia).

In addition to neuromuscular and neuropsychiatric abnormalities, cardiac conduction abnormalities and dysrhythmias may occur. The most common cardiac manifestation is QT prolongation, but bradycardia, congestive heart failure, hypotension, and triggered ventricular dysrhythmias, including torsades de pointes, may occur (Fig. 166.4).

In patients with chronic hypocalcemia, skin and ophthalmologic abnormalities may become notable. Cataracts in the lenses of the eyes, brittle nails, and coarse or dry hair and skin are typical.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Hypocalcemia found on routine laboratory evaluation should prompt evaluation for hypoparathyroidism, vitamin D deficiency, renal or liver failure, hypomagnesemia, and hyperphosphatemia. The emergency physician should consider ordering a total serum calcium or ionized calcium level in patients with a new seizure, psychosis or altered mental status, extrapyramidal symptoms, paresthesias, muscle spasms, congestive heart failure, prolonged QTc interval, or torsades de pointes.

In patients requiring massive blood transfusion, hypocalcemia should be prevented by regular assessment of calcium levels and early administration of intravenous calcium. Calcium administration should be performed with caution in hypocalcemic patients being treated with digoxin because of the risk for precipitation of digoxin toxicity.
The goals of therapy for hypocalcemia are to stop the uncomfortable symptoms of tetany and muscle spasm and prevent seizures, dangerous dysrhythmias, and laryngospasm. Severe, symptomatic hypocalcemia should be treated with a 10% intravenous solution of calcium gluconate or calcium chloride. The 10% solution of calcium chloride contains nearly three times the elemental calcium per milliliter as the 10% solution of calcium gluconate (Table 166.3). The dose of 10% calcium gluconate is 10 to 30 mL infused intravenously over a 10-minute period (provides 93 to 279 mg of elemental calcium). The dose of 10% calcium chloride is 10 mL infused intravenously over a 10-minute period (provides 270 mg of elemental calcium). The effects of a single bolus administration of intravenous calcium are temporary, so repeated boluses or a continuous infusion may be required in the setting of severe hypocalcemia or an ongoing process of calcium loss (pancreatitis or after parathyroidectomy). The rate of continuous infusion of calcium gluconate is 0.5 to 1.5 mg/kg/hr of elemental calcium, and it is generally supplied as 100 mL of 10% calcium gluconate in 900 mL of 5% dextrose in water (0.5 to 1.5 mL/kg/hr). Calcium chloride should be administered through a central vein. It is highly irritating to smaller peripheral veins and can cause phlebitis, and extravasation into subcutaneous tissues can result in significant local tissue necrosis.

Supplementation of calcium and vitamin D is the mainstay of therapy for chronic hypocalcemia. Virtually all forms of chronic hypocalcemia are associated with some degree of vitamin D deficiency. Vitamin D is available in a variety of forms. Selection of the appropriate form is based on the underlying cause of the vitamin D deficiency and the patient’s ability to appropriately hydroxylate the supplement in the liver and kidney (Table 166.4).

Oral calcium is available as a variety of salts, each with a different concentration of elemental calcium (Table 166.5). Calcium carbonate is generally preferred because it has the highest concentration of elemental calcium per tablet and thus fewer tablets are required to reach the appropriate dose of 1 to 1.5 g of elemental calcium daily.17 In the elderly, calcium citrate is preferred because it is more easily absorbed in the setting of low gastric acid.18

Patients with mild, chronic, and asymptomatic hypocalcemia can follow up with their primary physician as an outpatient. Initiation of calcium and vitamin D supplementation should be considered for symptomatic individuals in discussion with the patient’s primary physician.
Patients with profound or life-threatening symptoms or any patients requiring intravenous calcium supplementation should be admitted to a monitored setting and may require intensive care unit admission. Goals of inpatient admission include serial monitoring of calcium levels, further calcium replacement, and evaluation for critical illnesses and other causes of hypocalcemia. Telemetry monitoring should be used because of the risk for precipitation of ventricular arrhythmia.

Approximately 50% of total body magnesium is found in bone as a component of hydroxyapatite, similar to calcium. The remaining magnesium is located primarily intracellularly. Only 1% of total body magnesium is found in the extracellular space, with this amount further divided into protein-bound (30%) and ionized fractions.19

The balance between gastrointestinal absorption and renal excretion determines the serum magnesium level, with bone acting as a buffer to increase serum magnesium when levels are low. Neither gastrointestinal absorption nor renal excretion of magnesium is hormonally regulated. Circulating PTH regulates bone metabolism. Because serum magnesium levels influence release of PTH from the parathyroid glands, magnesium has an effect on serum calcium and phosphorus levels. The kidneys have the ability to reabsorb all but 0.5% of the filtered magnesium in the setting of hypomagnesemia and excrete up to 80% in the setting of hypermagnesemia.20 The normal serum range of magnesium is 1.8 to 2.5 mg/dL (0.74 to 0.94 mmol/L). No ionized magnesium laboratory test is available.

The recommended daily intake of elemental magnesium for adults is 320 mg for women and 420 mg for men. Dietary sources of magnesium include fish, nuts, cereals, and green vegetables. A variety of magnesium salt formulations are used therapeutically as laxatives and magnesium supplements (Table 166.6).

Magnesium acts as a cofactor for an extensive number of intracellular enzymatic reactions and is necessary for protein and DNA synthesis, as well as for adenosine triphosphate (ATP) function and glucose metabolism.21 It is also critical for neuromuscular conduction and muscle contraction.

HYPOMAGNESEMA

EPIDEMIOLOGY

Hypomagnesemia is defined as a serum magnesium level lower than 1.8 mg/dL, but most patients are not symptomatic until lower levels are reached. Two older studies demonstrated an incidence of hypomagnesemia of approximately 10% in the general hospitalized population and up to 65% in the intensive care unit patient population. It is unclear whether this incidence has changed over time. The incidence of hypomagnesemia in patients seen in the emergency department has not been determined.

PATHOPHYSIOLOGY

Magnesium is absorbed over the entire length of the gastrointestinal tract. Absorption is passive in the small bowel. Active transcellular absorption occurs in the colon. The direction of passive flow of magnesium can change to favor magnesium excretion into the bowel lumen in patients with conditions such as excessive diarrhea, vomiting, persistent nasogastric suction, or bulimia. Failure to properly absorb dietary magnesium because of malabsorption syndromes such as short gut syndrome, gastric bypass, steatorrhea, celiac disease, and radiation-induced enteritis can result in chronic hypomagnesemia.

Failure of renal magnesium absorption occurs in settings of osmotic diuresis as a result of hypercalcaemia, hyperglycaemia, and mannitol administration. Renal tubular, glomerular, and interstitial diseases may also result in an inability to properly reabsorb magnesium.

Hypomagnesemia may be triggered by acute pancreatitis secondary to saponification of fatty acids. A baseline poor dietary intake of magnesium from chronic alcohol abuse that precipitates pancreatitis may also contribute to hypomagnesemia in these patients.

Other causes of hypomagnesemia include acidosis, chronic alcoholism, non–magnesium-containing laxative abuse, and several drugs, including diuretics, aminoglycosides, amphotericin B, cisplatin, and cyclosporine.

PRESENTING SIGNS AND SYMPTOMS

Hypomagnesemia is highly correlated with abnormalities in other electrolytes. Hypokalemia is common because magnesium is necessary for proper function of the sodium-potassium adenosine triphosphatase (Na⁺,K⁺-ATPase) pump, which maintains an appropriate transcellular potassium gradient. Hypomagnesemia impairs secretion of PTH, causes renal and bone resistance to PTH, and causes intestinal resistance to vitamin D, thereby resulting in hypocalcemia.

Similar to hypocalcemia, hypomagnesemia results in significant neuromuscular hyperexcitability. The Chvostek and Trousseau signs may be present.

Magnesium has been demonstrated to be helpful in the treatment of dangerous arrhythmias, especially torsades de pointes and atrial fibrillation, thus suggesting that hypomagnesemia plays a role in the development of these arrhythmias. ECG changes associated with hypomagnesemia include prolongation of the PR and QTc intervals and the development of U waves (Fig. 166.5).

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Magnesium levels should be checked and normalized in patients with known or suspected hypocalcemia or hypokalemia and in patients with weakness or sensory-motor complaints. Assessment of the underlying cause of hypomagnesemia, especially in the setting of gastrointestinal losses, is necessary.
TREATMENT

Treatment of hypomagnesemia is slow intravenous infusion of 2 to 4 g of a 50% magnesium sulfate solution. It may be repeated as necessary, to a maximum dose of 8 g/day. This maximum dose is often exceeded in patients being treated with continuous infusions of magnesium sulfate for pre-eclampsia or tocolysis, so continuous monitoring for signs of hypomagnesemia are indicated in these patients.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Hospital admission is indicated for patients with life-threatening complications of hypomagnesemia, including seizures and cardiac arrhythmias. Mild, chronic hypomagnesemia can be treated on an outpatient basis with supplementation of magnesium salts. Dietary or lifestyle changes, including cessation of alcohol abuse, may be necessary to completely rectify the hypomagnesemia.

HYPERMAGNESEMIA

Epidemiology

Hypermagnesemia is defined as a serum magnesium level higher than 2.5 mg/dL. Hypermagnesemia is rare because of efficient renal excretion of excessive magnesium. In 1990 a published series of more than 1000 hospitalized adult patients demonstrated a 5.7% prevalence of hypermagnesemia in this population.25 There are multiple case reports in the emergency medicine literature of hypermagnesemia caused by iatrogenic and accidental overdoses.26

Pathophysiology

In the setting of iatrogenic or accidental overdose of magnesium, renal excretion of magnesium can be overwhelmed. The imbalance of absorption over excretion is worsened in the setting of acquired or chronic renal insufficiency, especially in patients with a glomerular filtration rate lower than 30 mL/min. Symptomatic hypermagnesemia is seen most often in the setting of iatrogenic administration of intravenous magnesium or after an overdose of magnesium-containing supplements or enemas. Concomitant use of anticholinergic or opiate medications that slow gastrointestinal motility can increase the risk for toxicity from magnesium-containing medications.27 Magnesium acts as a nonspecific calcium channel blocker. This property results in cardiac conduction abnormalities and hypotension in patients with acute elevations in magnesium.

Presenting Signs and Symptoms

The symptoms of hypermagnesemia progress in a dose-related fashion (Table 166.7). Early signs of hypermagnesemia

Fig. 166.5  A, Prolongation of the QT interval on an electrocardiogram in a patient with hypomagnesemia. B, Deterioration of the same patient’s rhythm to torsades de pointes, which was corrected with intravenous magnesium. (Courtesy Loren K. Rood, MD, Indiana University School of Medicine, Indianapolis.)
levels, especially with levels that place the patient at risk for hypotension, cardiac conduction abnormalities, or ventilatory failure.

Patients should be educated about the appropriate use of magnesium-containing antacids and laxatives and be made aware of the possibility of overdose when these medications are not used appropriately.

**Differential Diagnosis and Medical Decision Making**

Hypermagnesemia should be included in the differential diagnosis of patients with altered mental status, cardiac arrhythmias, hypotension, and shock. A directed history of use of over-the-counter antacids, laxatives, and enemas should be elicited when hypermagnesemia is suspected or found on laboratory analysis.

**Treatment**

The mainstay of treatment of hypermagnesemia is cessation of the use of any magnesium-containing medications. Fluid resuscitation with isotonic saline followed by diuretic therapy to encourage renal clearance of excessive magnesium is indicated. In patients with significant cardiac complications of hypermagnesemia, 10 to 20 mL of 10% calcium gluconate should be administered and repeated every 5 to 10 minutes as needed. Intravenous calcium administration antagonizes the natural calcium channel–blocking properties of magnesium. Hemodialysis may be required in the setting of hypermagnesemia and renal failure.

**Follow-up, Next Steps in Care, and Patient Education**

Hospital admission to a monitored setting or intensive care unit is indicated in the setting of severely elevated magnesium levels, especially with levels that place the patient at risk for hypotension, cardiac conduction abnormalities, or ventilatory failure.

Phosphorus

Eighty percent to 85% of total body phosphorus is contained in bone, complexed with calcium and magnesium as hydroxyapatite. Less than 1% of total body phosphorus is found extracellularly in plasma; the remaining phosphorus is located intracellularly. Phosphorus is the most abundant intracellular anion.

Phosphorus exists as organic and inorganic forms—it is the inorganic forms that are measured in the laboratory determination of serum phosphorus. Within the range of typical body pH, inorganic phosphorus exists as a balance between the phosphate anions $\text{H}_2\text{PO}_4^-$ and $\text{HPO}_4^{2-}$. At neutral pH the ratio of $\text{H}_2\text{PO}_4^-$ to $\text{HPO}_4^{2-}$ is 1:4. The normal serum range of phosphorus is 2.5 to 4.5 mg/dL (0.81 to 1.45 mmol/L).

Adequate phosphorus levels are important for multiple life-sustaining processes. Phosphorus is a key component of ATP, which is required for the generation of energy to carry out cellular processes. It is a part of the phospholipids that make up cell membranes, as well as DNA and RNA. Phosphorus is also necessary for 2,3-diphosphoglycerate in red blood cells, which facilitates release of oxygen from hemoglobin.

The balance between gastrointestinal absorption, bone anabolism and catabolism, and renal excretion determines serum phosphorus levels. Passive absorption of phosphorus from the diet occurs in the small intestines. Vitamin D–dependent active absorption also occurs and is responsible for approximately 30% of phosphorus absorption.

Foods rich in phosphorus include animal proteins, milk, eggs and multiple food preservatives.

Excretion of phosphorus occurs in the kidneys. Serum phosphorus is freely filtered by the glomeruli, with 80% to 90% being reabsorbed though an Na/Po cotransporter in the proximal tubules. PTH enhances the excretion of phosphorus by inhibiting this transporter. When PTH is released from the parathyroid gland, it acts on bone to release calcium and phosphorus. It also stimulates the kidney to increase production of 1,25-dihydroxyvitamin D, which results in increased gastrointestinal absorption of calcium and phosphorus. Both these mechanisms result in efficient increases in serum calcium, but the increase in serum phosphorus is modest. When combined with the increased excretion of phosphorus by the kidneys in response to PTH, the net effect of a rise in PTH is a decrease in serum phosphorus and an increase in serum calcium (see Fig. 166.1).
HYPOPHOSPHATEMIA

EPIDEMIOLOGY

Hypophosphatemia is rare in the general population, occurs in only 2% to 3% of hospitalized patients, but is much more common in the setting of critical illness, in which the incidence of phosphorus levels lower than 2.5 mg/dL ranges from 24% to 100%, depending on the intensive care unit population studied.

PATHOPHYSIOLOGY

There are three predominant mechanisms of hypophosphatemia. Acute hypophosphatemia occurs in the setting of forces that drive phosphate excessively from the extracellular space into the intracellular space. Respiratory alkalosis and treatment of diabetic ketoacidosis with insulin are two common examples of this form of hypophosphatemia. Refeeding syndrome, in which severely malnourished patients are fed a diet high in carbohydrate, is a rare cause of hypophosphatemia but may be encountered in the treatment of patients with severe anorexia nervosa.

Increased urinary excretion of phosphorus (as seen in primary and secondary hyperparathyroidism) and decreased intestinal absorption of phosphorus are the two other mechanisms of hypophosphatemia. Decreased dietary intake of phosphorus, excessive use of phosphate-binding antacids, vomiting, nasogastric suctioning, diarrhea, vitamin D deficiency, and malabsorption are all causes of decreased intestinal absorption of phosphorus. Chronic alcoholism can result in both dietary deficiency and excessive renal excretion of phosphorus.

PRESENTING SIGNS AND SYMPTOMS

The symptoms of hypophosphatemia worsen with falling serum levels. Patients with mild hypophosphatemia, or serum levels in the range of 2.0 to 2.5 mg/dL, are often asymptomatic. With moderate hypophosphatemia in the range of 1.0 to 2.0 mg/dL, patients may experience myalgias, muscle weakness, and anorexia. Severe hypophosphatemia, defined as a serum phosphorus level lower than 1.0 mg/dL, results in paresthesias, tremor, confusion, decreased deep tendon reflexes, cardiac arrhythmias and impaired cardiac contractility, impaired respiratory muscle function, seizures, and coma.

Rhabdomyolysis can occur in the setting of severe hypophosphatemia secondary to an inability to maintain muscle membrane integrity as a result of ATP deficiency.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

When hypophosphatemia is discovered, causes of respiratory alkalosis should be considered, including hyperventilation from salicylate toxicity, anxiety, pain, alcohol withdrawal, and chronic obstructive pulmonary disease.

Hypophosphatemia should be excluded in patients with myalgias, weakness, and rhabdomyolysis. Phosphorus levels should be monitored in patients being treated for diabetic ketoacidosis.

TREATMENT

Patients with severe phosphorus deficiency (serum phosphorus <1 mg/dL) should receive intravenous replacement in the form of either sodium phosphate or potassium phosphate. Potassium phosphate is preferred in patients with concomitant hypokalemia. Multiple studies have examined the safety of various doses and rates of administration of intravenous phosphorus supplementation. Doses up to 45 mmol and rates of 20 mmol/hr have been demonstrated to be safe when administered through a central venous catheter. The typical dose recommended for adults is 0.08 to 0.16 mmol/kg (2.5 to 5 mg/kg) administered over a period of 2 to 6 hours. Intravenous administration of phosphate-containing supplements can precipitate hypocalcemia, as well as hyperkalemia when potassium phosphate is used.

Mild hypophosphatemia (serum phosphorus level of 1 to 2 mg/dL) may be treated with oral phosphate-containing supplements at a dose of up to 1000 to 2000 mg daily, divided three or four times per day. A combination sodium phosphate and potassium phosphate tablet is available (K-Phos Neutral) that contains 250 mg of phosphorus, 298 mg (13 mEq) of sodium, and 45 mg of potassium (1.1 mEq). Cow’s milk is a rich dietary source of phosphorus that contains approximately 1 mg of phosphorus per 1 mL of milk.

FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients with severe hypophosphatemia are often critically ill and require admission for management of their underlying illnesses. Patients with severe, symptomatic hypophosphatemia should be admitted for replacement therapy and monitoring of electrolytes.

HYPERPHOSPHATEMIA

EPIDEMIOLOGY

Hyperphosphatemia is defined as a serum phosphorus level higher than 4.5 mg/dL, with severe hyperphosphatemia being defined as serum levels higher than 14 mg/dL. The most common cause of hyperphosphatemia is chronic renal failure requiring hemodialysis. Nearly 90% of these patients are managed with phosphorus-binding therapy and diets low in phosphorus to limit hyperphosphatemia.

PATHOPHYSIOLOGY

In patients with chronic renal failure, gastrointestinal absorption of phosphorus continues, but renal excretion ceases. Hemodialysis removes approximately 800 to 1000 mg of phos-
phosphorus per session, which is less than the typical dietary intake of phosphorus—a mainstay of treatment of hyperphosphatemia is limiting dietary intake and absorption of phosphorus. Excessive phosphorus combines with calcium to form salts that are deposited in the soft tissues of the body. Deposition in the soft tissues of the heart, kidneys, and vasculature has the potential to cause abnormalities in cardiac electrical conduction and cardiac muscle relaxation and contraction, as well as renal disease, coronary artery disease, and peripheral vascular disease. Some evidence indicates that calcium phosphate salt deposition increases mortality in patients undergoing hemodialysis.

Causes of acute elevations in phosphorus include hemolysis, tumor lysis syndrome, and rhabdomyolysis. All three conditions result in rapid breakdown of cellular membranes, which allows stores of intracellular phosphate to quickly be released into the extracellular space. Unless concomitant renal insufficiency is present or ongoing cellular destruction is occurring, the hyperphosphatemia in these conditions is self-limited because renal excretion soon exceeds extracellular phosphate shifting when supportive care is given.

Vitamin D toxicity and overuse of phosphate-containing antacids or enemas have been reported as causes of acute hyperphosphatemia resulting from excessive gastrointestinal absorption. An additional cause of chronic hyperphosphatemia is hypoparathyroidism. In the setting of impaired PTH secretion, renal excretion of phosphorus is decreased.

**PRESENTING SIGNS AND SYMPTOMS**

The symptoms of hyperphosphatemia are generally the consequence of associated renal failure and hypocalcemia and include altered mental status, seizures, dysrhythmias, prolongation of the QTc interval, muscle weakness, and neuromuscular excitability (see Box 166.2).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Acute hyperphosphatemia should prompt evaluation for acute renal failure, rhabdomyolysis, tumor lysis syndrome, and hemolysis. Calcium, magnesium, and potassium levels should be assessed in patients with hyperphosphatemia because many of these electrolyte abnormalities occur simultaneously.

**TREATMENT**

In the setting of acute hyperphosphatemia it is necessary to treat the underlying cause. This includes limiting further cell breakdown as much as possible in patients with hemolysis, tumor lysis syndrome, and rhabdomyolysis. Increasing renal excretion of phosphorus with fluid resuscitation, alkalization of urine with sodium bicarbonate, and diuretic therapy are also indicated.

In the setting of chronic hyperphosphatemia secondary to hypoparathyroidism or chronic renal failure, the mainstays of therapy are to reduce the dietary intake and gastrointestinal absorption of phosphorus.

Phosphate-binding salts are frequently used in the treatment of hyperphosphatemia in patients with renal failure. The cheapest and best-tolerated phosphate binders are calcium carbonate and calcium acetate. These medications may increase deposition of calcium phosphate salt in soft tissues, but considerable debate exists about the cost-effectiveness and side effect profile of alternative phosphate binders. Gastrointestinal side effects of nausea and diarrhea are common. Magnesium hydroxide, magnesium carbonate, sevelamer hydrochloride, sevelamer carbonate, and lanthanum are alternative phosphate-binding salts used for the treatment of hyperphosphatemia in patients with renal failure.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Patients with severe, acute hyperphosphatemia, especially in the setting of acute renal failure or symptomatic hypocalcemia, require admission for supportive care. Many patients with chronic hyperphosphatemia are asymptomatic and require only outpatient follow-up for dietary modifications or adjustment of phosphate-binding salt regimens.

Thyroid Disorders
Sarah Stewart de Ramirez and Frederick Korley

**KEY POINTS**

- Hypothyroidism secondary to iodine deficiency is the most common endocrine disorder worldwide.
- Primary hypothyroidism results from dysfunction of thyroid tissue. Secondary hypothyroidism is a component of panhypopituitarism that results from pituitary disease.
- Severe hypothyroidism is a rare condition characterized by altered mental status, hypothermia, and primary thyroid dysfunction. Myxedema is seen in most cases; true coma is not.
- Patients with suspected severe hypothyroidism should receive empiric, low-dose intravenous levothyroxine.
- Thyroid storm, the most extreme form of thyrotoxicosis, is a rapidly fatal condition.
- Antithyroid medication should be given at least 1 hour before the administration of iodine for the treatment of thyroid storm.
- Emergency department testing for thyroid disease includes serum thyrotropin, or thyroid-stimulating hormone, and free thyroxine measurements.

**PERSPECTIVE**

Hypothyroidism is a deficiency of thyroid hormones resulting in a hypometabolic state. Iodine deficiency accounts for most cases of hypothyroidism and goiter in underdeveloped countries; Hashimoto thyroiditis is a more commonly recognized cause in westernized societies.

Thyrotoxicosis describes any condition characterized by an excess of free thyroid hormones in the circulation. The term is frequently used interchangeably with hyperthyroidism; however, hyperthyroidism refers only to disease states in which the thyroid gland produces an excess of thyroid hormones.

**EPIDEMIOLOGY**

Abnormal thyroid function is by far the most common endocrine disorder worldwide and is second only to diabetes mellitus in the United States. Thyrotoxicosis is a rare condition that is 10 times more prevalent in women than in men (2% versus 0.2%). It is uncommon before the age of 15 years. Although most manifestations of thyrotoxicosis do not represent a true emergency, the extreme case of so-called thyroid storm does. Early detection and treatment of this condition may prevent progression to shock and death.

**ANATOMY**

The thyroid gland derives its name from the shape of the nearby thyroid cartilage (from the Greek, meaning “shield”). Although it varies, the isthmus is usually centered over the third tracheal ring. Normal adult thyroid dimensions are a height of 5 cm, thickness of 1.5 cm, isthmus thickness of 0.5 cm, volume of 10 cm, and weight of 12 to 20 g. Thyroid thickness greater than 2 cm is considered abnormal.

The thyroid gland is palpable on physical examination in nonobese patients; thyroid nodules and some cancers are sometimes noted on palpation. Rarely, ectopic thyroid gland tissue is found at the base of the tongue.

**PHYSIOLOGY**

Thyrotropin-releasing hormone (TRH) is synthesized in the hypothalamus and regulates the production of thyroid-stimulating hormone (TSH), or thyrotropin, in the anterior pituitary gland. Principal cells in the thyroid bind TSH, which activates the production and release of thyroid hormones.

The thyroid is highly efficient in its absorption and extraction of iodine. Iodine is added to tyrosine to make up diiodotyrosine (DIT); two molecules of DIT combine to form thyroxine (T4), much of which is stored in the thyroid gland. T4 is released into the circulation largely bound by thyroid-binding globulin (TBG). Even though levels of TBG vary widely, this protein is seldom involved in a disease process.

Triiodothyronine (T3) is formed by peripheral conversion of T4 in tissues. When compared with T4, T3 is four to six times more active, exhibits less affinity for TBG, and has a much shorter half-life (12 hours versus 6 days). T3 and T4 exert feedback on the hypothalamus and TRH levels, thereby completing a regulatory loop.

T3 and T4 stimulate metabolic activity in tissues throughout the body. Both hormones are associated with growth and development early in life.
GOITER

Goiter refers to a visible enlargement of the thyroid gland that may result from euthyroid, hyperthyroid, or hypothyroid states. The presence of a goiter mandates a detailed review of systems and appropriate thyroid testing to determine the functional status of the tissue. The most common cause of goiter is iodine deficiency. Other causes include Hashimoto thyroiditis, Graves disease, nodules, cancer, and lithium therapy.

Goiters are usually benign, but thyroid malignancy must be considered in each case. Three rare but potentially life-threatening emergencies can result from continued enlargement of a malignant goiter. First, partial or complete obstruction of the jugular veins may occur, especially in hypercoagulable patients. Clot extension from a partially obstructed jugular vein can impede venous drainage from the brain. Second, invasive or extremely large goiters have been reported to cause airway compromise. Third, malignant involvement of the carotid sheath structures can result in devastating morbidity.

HYPOTHYROIDISM

PATHOPHYSIOLOGY

Primary hypothyroidism implies a condition of thyroid tissue dysfunction. Causes include Hashimoto thyroiditis, surgical ablation, iodine I 131 ablation, and iodine deficiency. Idiopathic cases are frequently observed as well. The most common cause of hypothyroidism in industrialized countries is Hashimoto thyroiditis, an autoimmune disease of unclear cause.

Secondary hypothyroidism refers to pituitary dysfunction that results in a low TSH level and subsequent poor stimulation of otherwise normal thyroid tissue. Pituitary dysfunction generally affects more than one endocrine axis (panhypopituitarism); hypothyroidism is never the only resultant condition. Secondary hypothyroidism is seen with Sheehan syndrome and space-occupying lesions (adenomas) of the pituitary gland.

Hypothyroidism is 3 to 10 times more common in women than in men. Its incidence increases with age and obesity; 1% of young girls are affected as compared with 6% of older women. Smoking has been identified as an independent risk factor for hypothyroidism, but the reason for the observed association is unknown. Hypothyroidism has no racial or ethnic predilection. Symptoms of hypothyroidism are more apparent during the winter months in moderate and cold climates.

Iodine deficiency is the major worldwide cause of both hypothyroidism and cretinism; the latter is characterized by growth and mental retardation. Selenium deficiency appears to worsen the cretinism. Iodine deficiency is rare in the United States but affects approximately one in three persons worldwide, particularly in mountainous regions. Iodine deficiency has been decreasing because of supplementation programs sponsored by the World Health Organization. Excessive supplementation and diets high in seafood may contribute to thyroiditis.

CLINICAL PRESENTATION

Hypothyroidism is a deficiency of thyroid hormones that results in decreased metabolic activity. It mimics many conditions commonly encountered in the emergency department (ED) and is accompanied by a myriad of indolent symptoms (Boxes 167.1 and 167.2).

In a recent study of the incidence of newly diagnosed primary overt hypothyroidism in adults seen in a Taiwanese ED, the most common symptoms were fatigue (50%), dyspnea (45%), chest tightness (20%), constipation (14%), and cold intolerance (9%). The majority of these patients were seen during winter months. In only 21% was hypothyroidism diagnosed by the emergency physician.

Clinicians should maintain a high index of suspicion for hypothyroidism in patients with new-onset depression.

SEVERE HYPOTHYROIDISM (MYXEDEMA COMA)

Patients with severe hypothyroidism may have mild to moderate hypothermia, depression, lack of energy, and altered mental status. Myxedema coma is a misnomer often used for severe hypothyroidism; not all patients with severe hypothyroidism are truly comatose, whereas most (but not all) patients with hypothyroid coma have myxedema. Myxedema coma best describes a patient in extremis secondary to a severe hypothyroid state (Box 167.3).

DIAGNOSIS

Historical symptoms and physical signs suggestive of hypothyroidism justify testing. The incidence of this disease is so high in elderly women that screening of these patients, even though they are asymptomatic, is performed by many primary care physicians.

Markers of primary hypothyroidism include a high serum TSH level and a low unbound free T4 (FT4) level in the presence of classic signs and symptoms. Symptomatic patients with even minimally elevated TSH may benefit from low-dose thyroxine supplementation.

There is disagreement about the level of TSH and FT4 required to begin treatment in asymptomatic individuals. Several sources recommend thyroxine supplementation for asymptomatic patients with a serum TSH level that is three times the upper limit of normal, regardless of a low or low-normal FT4 level.

Secondary hypothyroidism, generally a component of panhypopituitarism, is marked by low TSH, low FT4, and low serum cortisol levels. Both thyroid and steroid replacement is required, and further diagnostic evaluation (e.g., pituitary imaging, endocrine testing) is indicated.

Hypothyroid patients may also have low serum sodium levels and elevated total cholesterol, both of which may resolve with thyroxine therapy.

TREATMENT

MILD HYPOTHYROIDISM

Treatment is initiated with levothyroxine, 1.6 mcg/day. In patients with primary thyroid disease, TSH should be monitored every 30 days. Those being treated with levothyroxine do not require monitoring of FT4. Although mild hypothyroidism is not an emergency per se, initiating treatment for symptomatic patients (in consultation with an endocrinologist) is appropriate if the diagnosis is established in the ED. Routine follow-up is necessary.

SEVERE HYPOTHYROIDISM (MYXEDEMA COMA)

Management of severe hypothyroidism consists of standard ED resuscitation measures, including consideration and empiric treatment of potential sepsis. The only treatment step specific for severe hypothyroidism is intravenous (IV) administration of levothyroxine. Empiric administration of low-dose levothyroxine is appropriate in patients in whom a serum TSH level cannot be obtained in timely fashion. ED treatment of myxedema coma is summarized in Box 167.4.

Note that previous studies have deemed T3 supplementation to be unsafe; however, because of the low incidence of myxedema coma, large clinical trials of T3 have not been performed.

DISPOSITION

Patients with mild hypothyroidism may be managed as outpatients with referral to a primary care physician and an endocrinologist. Patients with severe hypothyroidism should be admitted to the hospital for further management.

THYROTOXICOSIS

Thyrotoxicosis is caused by at least one of four potential mechanisms:

1. Overproduction of thyroid hormones by the thyroid gland
2. Unregulated release of thyroid hormones secondary to destruction of thyroid cells (thyroiditis)
3. Ingestion of thyroid hormones
4. Production of thyroid hormones from ectopic foci (Fig. 167.1)

CAUSES

GRAVES DISEASE

Graves disease, the most common cause of hyperthyroidism, accounts for approximately 60% to 80% of cases of hyperthyroidism in the United States. It is the most common autoimmune disorder in North America. In this disease, thyroid-stimulating immunoglobulins (an IgG antibody) bind to and activate thyrotropin receptors on thyroid cells, thereby mimicking the action of TSH. Continued binding of the antibody to the TSH receptor leads to excessive production of T3 and thyroid enlargement.4

THYROIDITIS

Thyroiditis describes conditions in which inflammatory changes lead to the destruction of thyroid cells, which results in the excess release of thyroid hormones. This is followed by depletion of circulating thyroid hormones and subsequent euthyroid and, eventually, hypothyroid states.

Autoimmune destruction of thyroid cells is seen in patients with Hashimoto thyroiditis, painless sporadic thyroiditis, and painless postpartum thyroiditis. Hashimoto thyroiditis is characterized by high levels of serum antithyroid antibodies. This
condition is the most common cause of hypothyroidism in the United States. Painless postpartum thyroiditis occurs in up to 10% of American women. Its onset is usually 1 to 6 months after delivery. Approximately 80% of women recover normal thyroid function within a year. The chance of recurrence with subsequent pregnancies is 70%.

Painful subacute (de Quervain) thyroiditis is the most common cause of thyroid pain. It is a self-limited disorder that is frequently preceded by an upper respiratory infection. Suppurative thyroiditis is a rare condition that is caused by bacterial, fungal, or mycobacterial infection of the thyroid gland. It may be seen in severely immunocompromised patients. Additionally, amiodarone and lithium can cause drug-induced thyroiditis.

NON–THYROID-STIMULATING HORMONE–MEDIATED HYPERTHYROIDISM

Hyperthyroidism is sometimes caused by a benign, monoclonal, autonomously secreting thyroid nodule known as toxic adenoma (Plummer disease). When more than one nodule is present, it is referred to as toxic multinodular goiter. This condition is the second most common cause of thyrotoxicosis and accounts for 5% to 15% of all cases of thyrotoxicosis. In the United States, toxic multinodular goiter is primarily seen in persons older than 50 years and accounts for more than 40% of all cases of thyrotoxicosis in this age group. Similarly, thyroid follicular cell cancer can likewise lead to excessive production of thyroid hormones.

OTHER CAUSES

Increased secretion of thyrotropin by a pituitary adenoma can also cause thyrotoxicosis. Alternatively, thyroid hormones may be produced from sites outside the thyroid gland. This occurs in cases of metastatic follicular thyroid carcinoma and struma ovarii (an ovarian teratoma that contains thyroid tissue).

Human chorionic gonadotropin can also stimulate TSH receptors to produce excess thyroid hormones in patients with gestational trophoblastic disease and hyperemesis gravidarum.

CLINICAL PRESENTATION

Thyrotoxicosis can be asymptomatic (subclinical hyperthyroidism) or feature mild, moderate, or severe symptoms that result from a surge in catecholamines. Patients with classic thyrotoxicosis may appear nervous, irritable, and tremulous. They may complain of unintentional weight loss, palpitations, exertional dyspnea, heat intolerance, thinning of their hair, irregular menses, increased frequency of bowel movements, and sleep disturbance. On physical examination, patients may have a palpable goiter, warm moist skin, sinus tachycardia out of proportion to fever, or atrial fibrillation on electrocardiography.

Patients with Graves disease may have the following physical findings: goiter, periorbital ecchymosis, chemosis, proptosis, lid retraction, and lower extremity edema. Patients with painful subacute thyroiditis may have fever, malaise, myalgias, fatigue, and neck pain in addition to the symptoms of thyrotoxicosis mentioned previously.

VARIATIONS

Pregnancy

Women of childbearing age represent the peak incidence of thyroid disease; however, this presents a clinical dilemma
Patients with painful subacute thyroiditis will have an elevated serum erythrocyte sedimentation rate and C-reactive protein levels. **Box 167.7** lists the tests that should be obtained in the ED for patients in thyroid storm. If thyrotoxicosis is suspected, an endocrinologist may schedule further testing to confirm the diagnosis and determine the cause. Such tests may include measurement of total T₃, thyroid autoantibodies, and radioactive iodine uptake; ultrasonography; and fine-needle biopsy.

**TREATMENT**

A beta-blocker should be started in patients with mild symptoms to provide symptomatic relief from tremors, palpitations, tachycardia, sweating, and anxiety (Fig. 167.3). It is important to withhold other treatment until the cause of the thyrotoxicosis is confirmed. Treatment options include antithyroid medications, radioactive iodine ablation, and surgery. The risks and benefits of these treatments must be weighed by the patient and the endocrinologist.

Treatment of most forms of thyroiditis is supportive. Patients with persistent tachycardia should be given beta-blockers. Patients with painful subacute thyroiditis should be treated with nonsteroidal antiinflammatory drugs, IV fluids, and beta-blockers.

**THYROID STORM**

Medications are administered to stop the synthesis, release, and peripheral effects of thyroid hormones. The order in which antithyroid medications and iodide are given is very important. First, the synthesis of new thyroid hormone is blocked by the oral administration of 200 mg of propylthiouracil (PTU) every 4 hours or 25 mg of methimazole every 6 hours. (PTU and methimazole should not be given together.) In addition to

---

**DIAGNOSIS**

The most useful ED tests for diagnosing thyrotoxicosis are TSH and FT₄ measurements. The algorithm in **Figure 167.2** provides an interpretation of variable TSH, FT₄, and free triiodothyronine (FT₃) levels. **Box 167.6** lists conditions that should be considered in the differential diagnosis.
Thyroid disorders

Patients with mild symptoms of thyroid disease may be discharged with beta-blocker therapy and primary care follow-up instructions. Those with moderate symptoms should be admitted to the hospital for supportive care and endocrinology consultation. Patients with severe symptoms or thyroid storm should be admitted to the intensive care unit.

Adrenal Crisis

Brian K. Nelson

KEY POINTS

- Adrenal crisis is an uncommon cause of shock.
- An inappropriate adrenal response may contribute to shock in patients with sepsis, trauma, myocardial infarction, and other conditions associated with extreme physiologic stress.
- The diagnosis of acute adrenal crisis may be challenging because the symptoms are often nonspecific (e.g., weakness, fatigue, gastrointestinal symptoms, abdominal, flank, or back pain).
- Laboratory findings include hyponatremia, hyperkalemia, hypoglycemia, lymphocytosis, and eosinophilia.
- Adrenal crisis may result from either primary adrenal insufficiency or secondary adrenal suppression as a result of exogenous steroids or from failure of the hypothalamic-pituitary-adrenal axis. In the latter, mineralocorticoid replacement is not necessary, but thyroid supplementation may be lifesaving.
- Emergency department management includes aggressive fluid resuscitation, correction of electrolyte abnormalities, maintenance of euglycemia, and administration of glucocorticoids and mineralocorticoids.
- Treatment should begin with initial suspicion of adrenal crisis, not at the time of laboratory confirmation. Interventions are indicated when the cause of the shock is obscure, the patient fails to respond to volume and pressors within 1 hour, or the diagnosis of adrenal insufficiency is confirmed.

PATHOPHYSIOLOGY

Adrenal insufficiency is an uncommon disease with nonspecific manifestations, including fatigue, nausea, vomiting, hyperpigmentation, hypotension, and weight loss. Failure to recognize and treat the often subtle signs and symptoms of adrenal crisis can result in significant morbidity and mortality.

Acute adrenal crisis may complicate a variety of conditions that are related to an inadequate neuroendocrine response to stress. Crisis may result from primary adrenal failure or may occur secondary to failure of the hypothalamic-pituitary-adrenal axis. Failure may result from a primary process or may be secondary to suppression by exogenous steroid administration.

ANATOMY

The adrenal glands are retroperitoneal structures that lie within the fascia of Gerota, superior and medial to the kidneys. Their blood supply arises from the aorta and the renal and inferior phrenic arteries. Blood flows from the arteries through a sinusoidal system and collects in single veins draining into either the inferior vena cava or the left renal vein for the right and left adrenals, respectively. The adrenal glands are encapsulated and divided into a cortex and a catecholamine-producing medullary zone. The cortex is further subdivided into the zona glomerulosa, which produces mineralocorticoids, and the zona fasciculata and zona reticularis, which secrete glucocorticoids and androgens.

ADRENAL PRODUCTS

Cholesterol is converted to pregnenolone, an adrenal precursor of more than 50 separate chemical pathways and by-products. Of these, the most clinically important glucocorticoid is cortisol, the most important androgen is dehydroepiandrosterone acetate, and the most important mineralocorticoid is aldosterone.
FEEDBACK LOOPS

Adrenocorticotropic hormone (ACTH) is the major regulator of cortisol and adrenal androgen production. ACTH is regulated by corticotropin-releasing hormone and antidiuretic hormone. Cortisol levels feed back on corticotropin-releasing hormone production. The renin-angiotensin system regulates aldosterone production.

CORTISOL PHYSIOLOGY

ACTH and cortisol levels vary by circadian rhythm. They both reach their nadir at about 4 AM and peak at approximately 8 AM. Serum levels also peak within minutes of stress-induced release of corticotropin-releasing hormone in the central nervous system. Most circulating cortisol is bound to protein (75% to corticosteroid-binding globulin and 15% to albumin); only 10% is “free cortisol” (unbound).

TARGETS OF ACTION

Mineralocorticoids act at the renal tubules to maintain Na+, K+, and water balance. Glucocorticoid subunits enter various cell nuclei and modify the expression of a wide range of genes in different organ systems (Table 168.1). Cortisol is capable of targeting the mineralocorticoid receptors at pharmacologic doses, although at physiologic levels it is converted to inactive cortisone on entering the kidney.

CLINICAL APPLICATION

Adrenal insufficiency is classified as primary, secondary, or relative. Causes of primary insufficiency are numerous (Table 168.2). Secondary insufficiency is most commonly due to exogenous steroid withdrawal. Relative adrenal insufficiency occurs in individuals who may have normal glucocorticoid levels but exhibit an inadequate response of the hypothalamic-pituitary-adrenal axis to major stress.

Relative adrenal insufficiency is one of the most important subtypes of adrenal insufficiency encountered in emergency medicine. It should be considered in any seriously ill patient who fails to respond to the usual interventions. This condition is most commonly observed in patients with severe sepsis, but it may develop in any patient with uncompensated shock that is resistant to adequate fluid resuscitation and vasopressors.

PRESENTING SIGNS AND SYMPTOMS

Patients with primary and secondary adrenal insufficiency typically have chronic complaints. Those with primary disease may exhibit weakness, fatigue, anorexia, nausea, vomiting, weight loss, hypotension, hyperpigmentation, hyponatremia, and hyperkalemia. The hyperpigmentation is initially generalized and later becomes evident in the mucous membranes, palmar creases, nail beds, and nipples. Gastrointestinal disturbances are present in about half of patients with postural symptoms. Salt craving is a less common complaint. Associated endocrinopathies may complicate the initial findings (see Table 168.2).

Patients with secondary adrenal insufficiency typically have normal mineralocorticoid levels and therefore less serious volume or electrolyte abnormalities. The chronic findings of secondary adrenal insufficiency are classically nonspecific in nature and consist of weakness, lethargy, anorexia, and myalgias. Hyperpigmentation is not a feature of secondary adrenal insufficiency.

TYPES OF ADRENAL INSUFFICIENCY

ACUTE ADRENAL INSUFFICIENCY

Although most patients with subacute or chronic adrenal insufficiency are identified during outpatient evaluation, some patients in whom it has not yet been diagnosed will be encountered in the emergency department (ED) with acute insufficiency. Such patients may have either primary or secondary insufficiency and seek care because of physiologic stress that cannot be met with appropriate rises in adrenal hormones. The majority of these patients will exhibit shock, nausea, vomiting, confusion, fever, and abdominal pain.

ACUTE ADRENAL HEMORRHAGE

Acute adrenal hemorrhage is a rare condition that should be suspected in seriously ill postoperative patients and in those with antiphospholipid syndrome, severe sepsis, or shock. Such patients have the general features of acute adrenal crisis and focal findings of abdominal, flank, or back tenderness. Abdominal examination may reveal a surgical abdomen.

Treatment should begin on suspicion of this diagnosis. Early intervention has been shown to reduce mortality in postoperative patients and those with antiphospholipid syndrome; the timing of therapy does not appear to affect the usually high mortality associated with this condition in patients with sepsis or severe shock. Only a minority of patients will be found to have hyponatremia or hyperkalemia. The diagnosis is confirmed through imaging studies2,3 (Fig. 168.1).
disease, the normal range of serum cortisol levels in response to stress or corticotropin testing in the seriously ill, the dose of corticotropin to be administered for testing, and the indications for, optimal dosing of, and desired efficacy of steroids in the critically ill.4-13,15

The use of steroids for sepsis has been explored. Well-designed trials of supraphysiologic doses of steroids have demonstrated no beneficial effect. Two recent randomized clinical trials of corticosteroids in septic shock populations with new criteria for relative adrenal insufficiency and lower dosages of steroids have been completed with conflicting results. Entry criteria differed somewhat between the studies. At present, the following conclusions can be drawn:

1. There is evidence that the use of “low-dose” hydrocortisone may be beneficial for severe septic shock refractory to fluid resuscitation and vasopressors if given early in the course of the shock (within 8 hours).15

2. Delayed administration of steroids in resuscitated patients is not beneficial and may be harmful.6

**RELATIVE ADRENAL INSUFFICIENCY IN CRITICALLY ILL PATIENTS**

It is estimated that approximately 2% of the U.S. population has an inadequate adrenal response to stress. The incidence of relative adrenal insufficiency in critically ill patients has been reported to be as low as 0% and as high as 77%.12,15

Diagnosis and treatment of relative adrenal insufficiency are controversial. Disagreement exists about the incidence of

* See references 4 to 14.

**Fig. 168.1** Coronal section showing left adrenal hemorrhage. The right adrenal demonstrates a usual inverted “Y” appearance.

**DRUG-INDUCED ADRENAL INSUFFICIENCY**

A number of medications may cause reversible adrenal insufficiency. Examples include ketoconazole, rifampin, phenytoin, and etomidate. Use of etomidate as an induction agent for rapid-sequence intubation (RSI) of critically ill patients is controversial. A single dose can cause relative adrenal insufficiency for up to 48 hours, but the clinical significance of this degree of suppression is unclear.14,16,17 In two retrospective and one prospective observational studies of single-dose etomidate RSI in the ED, no significant difference was found in in-hospital mortality.18-20 In a randomized study of trauma patients requiring RSI, those receiving etomidate had longer intensive care unit and hospital length of stay and more ventilator days and required more red blood cell transfusions and fresh frozen plasma.21 In an a priori substudy of the CORTICUS trial, use of etomidate in the 72 hours before study inclusion was associated with higher mortality.22 However, the
Adrenal function testing begins with the administration of 250 mcg of synthetic ACTH. A rise in serum cortisol to greater than 8 mcg/dL within 30 minutes is considered a normal response. Such a finding excludes primary insufficiency but does not evaluate hypothalamic-pituitary-adrenal axis–related causes of secondary insufficiency. The hypothalamic-pituitary-adrenal axis is usually tested afterward with a metyrapone or insulin-hypoglycemia challenge. Critically ill patients in whom serum cortisol fails to rise by more than 9 mcg in serial measurements should be considered nonresponders who require glucocorticoid therapy.

The classic finding of concurrent hyponatremia and hyperkalemia may indicate subacute or chronic adrenal insufficiency in the appropriate clinical setting. Imaging studies may identify adrenal tumors or hemorrhage that may be responsible for the insufficiency. Incidental adrenal pathology is observed in approximately 2% of abdominal scans. Tumors may be benign or malignant, primary or metastatic.¹⁹,²⁰

**TREATMENT**

For the purposes of immediate resuscitation before testing, a functional parameter is used: a patient in shock who fails to respond to fluids and vasopressors within 1 hour should be treated empirically for adrenal insufficiency.

**HYDROCORTISONE**

Patients with adrenal crisis should receive intravenous (IV) hydrocortisone replacement. The initial adult dose of hydrocortisone is 100 mg every 6 hours. In children the dose can be given as 50 to 75 mg/m²/day divided into four IV doses. The dose can be tapered as the patient’s condition stabilizes. Severely ill patients, particularly those exhibiting septic shock, may require longer durations of treatment.

**DEXAMETHASONE**

Stable patients may be given IV dexamethasone, 4 mg every 6 hours. Dexamethasone allows a corticotropin stimulation test to be conducted because it does not immediately suppress hypothalamic activity. Dexamethasone has little mineralocorticoid activity, however, and should therefore be avoided in patients with adrenal crisis.

**FLUDOCORTISONE**

Mineralocorticoid therapy is available only in oral form in the United States. Parenteral hydrocortisone, 100 mg given every 6 hours, has sufficient mineralocorticoid activity to adequately treat critically ill patients who cannot tolerate oral medications. As their condition stabilizes and patients are able to take medications by mouth, hydrocortisone is tapered and oral fludrocortisone, 0.05 to 0.1 mg, is added each morning. Patients with secondary adrenal insufficiency do not require mineralocorticoids.

**OTHER TREATMENT CONSIDERATIONS**

Patients with primary failure of the hypothalamic-pituitary-adrenal axis may have concurrent clinical hypothyroidism and require thyroxine supplementation. All patients with adrenal insufficiency should undergo prompt correction of volume status, electrolyte imbalance, and hypoglycemia.

---

**DIAGNOSTIC TESTING**

Empiric treatment of patients with suspected acute adrenal crisis should not be delayed for confirmatory laboratory testing. The initiation of glucocorticoid therapy should be accompanied by a concurrent, single measurement of serum cortisol. Levels below 15 mcg/dL in a patient with severe sepsis or shock suggest adrenal crisis. Laboratory standards for adrenal function were established in normal subjects and are thus not applicable to populations under physiologic stress.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of adrenal crisis includes most other conditions known to cause shock (Box 168.1). These same conditions may induce relative adrenal insufficiency, and therefore their diagnosis does not exclude a concurrent adrenal crisis.

</tr>
</tbody>
</table>

**RED FLAGS**

Conditions that promote shock may induce concurrent relative adrenal insufficiency; diagnosis of one condition does not exclude a second occult disease.

Induction doses of etomidate may cause relative adrenal insufficiency for up to 72 hours after rapid-sequence intubation in critically ill patients.
Patients with incidental laboratory findings may be referred for outpatient management if they have no clinical evidence of acute adrenal insufficiency or excess, aldosterone excess, or pheochromocytoma. Adrenal masses larger than 6 cm will probably be removed, as well as those that demonstrate endocrine activity.

**PRIORITY ACTIONS**

**Do:**
- Use a bedside glucometer and administer 50% dextrose in water as needed.
- Administer a 20-mL/kg bolus of normal saline.
- Begin vasopressors when shock persists despite volume resuscitation.
- Check serum electrolytes, thyroid-stimulating hormone, and free thyroxine levels.
- Check a random serum cortisol level.
- Administer 100 mg of hydrocortisone intravenously every 6 hours.
- Search for comorbid conditions, particularly causes of sepsis.

**Do Not:**
- Withhold glucocorticoids while awaiting laboratory results.
- Attempt endocrine stimulation testing in acutely ill patients.

**Disposition**
- Patients with shock or obtundation should be admitted to a critical care unit. Those who quickly respond to treatment may be considered for admission to an unmonitored floor.
- Patients with mild symptoms, known disease, and reliable follow-up can be treated in the emergency department and be discharged to the care of their personal physician (see Tables 168.1 and 168.2).

**PATIENT TEACHING TIPS**

- Absolute lifelong compliance with outpatient medication regimens is mandatory.
- Double the steroid doses during times of physiologic stress and minor illness.
- Seek medical attention if nausea and vomiting occur; they may be symptoms of adrenal crisis and might prevent tolerance of needed oral medications.

ADRENAL CRISIS

Rhabdomyolysis

Bruce D. Adams and Charles B. Arbogast

DEFINITION AND EPIDEMIOLOGY

Rhabdomyolysis is a condition characterized by injury to skeletal muscle that results in release of the intracellular contents into the extracellular fluid and circulation. Authoritative thresholds for creatine kinase (CK) range between 1000 and 10,000 U/L, but some definitions additionally mandate the presence of myoglobinuria (Box 169.1).

Rhabdomyolysis can occur secondary to trauma, exertion, muscle hypoxia, genetic defects, infections, changes in body temperature, metabolic and electrolyte disorders, drugs and toxins, and idiopathic causes. Various categorizations of rhabdomyolysis have been proposed: traumatic versus atraumatic, reversible versus irreversible, endogenous versus exogenous, and hereditary versus acquired. More than half of all cases of rhabdomyolysis are multifactorial (Box 169.2).

Rhabdomyolysis afflicts more than 25,000 individuals in the United States each year. Morbidity and mortality vary tremendously depending on etiology, available treatment, time course, and comorbid factors. Acute kidney injury is a potential major complication of rhabdomyolysis and worldwide occurs in 15% to 45% of cases. In contrast, 7% to 10% of cases of acute kidney injury in the United States are caused by rhabdomyolysis.¹ Mortality generally ranges from 3% to 10% but can be as high as 25% in mass casualty incidents that involve crush injuries.

Certain populations appear to be at increased risk for the development of rhabdomyolysis. Alcohol and recreational drug abusers, patients taking numerous medications, military recruits, and athletes training well above their level of conditioning are of particular concern. Athletes with a predominance of type II fast twitch fibers (typically sprinters and weight lifters) are at higher risk for rhabdomyolysis than are those with a majority of type I slow twitch fibers (e.g., marathon runners). A large number of genetic disorders are linked to rhabdomyolysis as well.

PATHOPHYSIOLOGY

Rhabdomyolysis is a condition characterized by injury to skeletal muscle that alters the integrity of the cell membrane. Despite the large number of causes of rhabdomyolysis, the underlying pathology involves direct damage to the sarcolemma or depletion of adenosine triphosphate (ATP) within the myocyte resulting in an unregulated increase in intracellular calcium. This leads to constant contraction, energy depletion, and eventual necrosis and death of the muscle cell with release of its intracellular contents into the circulation.² The most important products released include potassium, phosphorus, myoglobin, CK, aspartate transaminase, alanine transaminase, lactate dehydrogenase, urate, cytokines, and purines.

CAUSES OF RHABDOMYOLYSIS

DIRECT MUSCLE INJURY

Traumatic rhabdomyolysis is primarily the result of motor vehicle crashes, occupational injuries, or environmental tragedy (i.e., mine collapse, earthquakes, war). Muscle compression may also occur during torture and abuse, long-term confinement in the same position (as with orthopedic injuries or during restraint of psychiatric patients), prolonged surgical interventions with improper positioning (high lithotomy or

KEY POINTS

- The most common causes of rhabdomyolysis include substance abuse, direct muscle injury, infection, strenuous physical activity, medications, and toxic ingestions.
- Only 50% of patients with rhabdomyolysis complain of specific muscle symptoms, and less than 10% have muscle tenderness on examination.
- Acute kidney injury is a potential major complication of rhabdomyolysis.
- Aggressive fluid resuscitation decreases the likelihood of kidney injury.
- Rhabdomyolysis and crush syndrome often emerge as the leading causes of delayed mortality in mass casualty incidents involving building collapse.
- Early hemodialysis is indicated when severe hyperkalemia, refractory metabolic acidosis, or crush injury is present.
- Use of supplemental calcium or loop diuretics should be avoided if possible in the setting of rhabdomyolysis.
## BOX 169.1 Suggested Definition of Clinical Rhabdomyolysis

Absolute creatine kinase > 15,000 U/L
or
Creatine kinase > 5000 U/L and any of the following:
- Crush injury
- Acute kidney injury or overt failure
- Myoglobinuria
- Acidosis, disseminated intravascular coagulation, hypocalcemia, or hyperkalemia
- Massive muscle injury
- Prolonged extrication or initial evaluation delayed longer than 4 hours

## BOX 169.2 Causes of Rhabdomyolysis

### Direct Muscle Injury
- Burns
- Electrical injury
- Lightning injury
- Sickie cell disease
- Trauma, crush, compression

### Ischemic Injury
- Compartment syndrome
- Compression
- Sickie cell disease
- Vascular occlusion (embolism, thrombosis)
- Vasculitis

### Excessive Muscular Activity
- Acute dystonia
- Contact sports
- Delirium tremens
- Isometric exercise
- Lethal catatonia
- Overexertion in untrained athletes
- Psychosis
- Seizures
- Sports, basic training, marathon running
- Status asthmaticus

### Drugs of Abuse
- Amphetamines
- Caffeine
- Cocaine
- Methylenedioxymethamphetamine (MDMA; “ecstasy”)
- Ethanol
- Gasoline
- Heroin
- Lysergic acid diethylamide (LSD)
- Marijuana
- Mescaline
- Methamphetamines
- Opiates
- Phencyclidine (PCP; “angel dust”)
- Toluene

### Medications
- Amphotericin B
- Antihistamines
- Azathioprine
- Barbiturates
- Benzodiazepines
- Butyrophenones
- Chlorpromazine
- Cimetidine
- Codeine
- Clofibrate
- Colchicine
- Corticosteroids
- Cotrimoxazole
- Cyclosporine
- Erythromycin
- 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors
- Inhalational anesthetics
- Isoniazid
- Itraconazole
- Lindane
- Lithium
- Lovastatin
- Methadone
- Monoamine oxidase inhibitors
- Narcotics
- Neuroleptic agents
- Organic solvent
- Pentamidine
- Phenothiazine
- Phenylpropanolamine
- Phenytoin
- Procainamide
- Quinine
- Salicylates
- Serotonergic agents
- Succinylcholine
- Theophylline
- Total parenteral nutrition

---

**INFECTION**

Bacterial, viral, parasitic, and rickettsial infections have been associated with rhabdomyolysis. The most common viral cause is influenza. Viruses cause rhabdomyolysis both by direct muscle invasion and by endotoxins and exotoxins that are responsible for skeletal muscle injury and subsequent release of myoglobin. *Legionella* is the most common bacterial cause, with its myotoxic effects mediated through an
endotoxin. *Salmonella* and *Streptococcus* also induce rhabdomyolysis through direct myocyte invasion and inhibition of glycolytic enzymes.

**EXCESSIVE MUSCLE CONTRACTION**

Strenuous exercise by both trained and untrained athletes can cause rhabdomyolysis. The degree of muscle injury is related to the duration and intensity of the exercise, and damage is frequently confined to the lower extremities. Muscle injury is exacerbated by hot, humid conditions; lack of heat acclimatization; prolonged, profuse sweating; and insufficient intake of salt. Patients at increased risk include athletes, marathon runners, new military recruits (“march myoglobinuria”), outdoor workers, and persons unaccustomed to strenuous exercise (“white collar rhabdomyolysis”).

Pathologic causes of excessive muscle activity such as status epilepticus, myoclonus, dystonia, tetanus, chorea, and mania also lead to rhabdomyolysis. Additionally, patients suffering from a multitude of intoxications, including isoniazid, strychnine, amoxapine, loxapine, theophylline, water hemlock, and lithium, may experience excessive motor activity and seizures producing rhabdomyolysis.

Excessive muscle activity causes rhabdomyolysis through dehydration, increased activity of heat-sensitive degradative enzymes.

</table>
enzymes, and depletion of cellular energy (ATP) with prolonged exercise. These insults lead to failure of the sarcolemmal sodium-potassium adenosine triphosphatase (Na⁺,K⁺-ATPase) and Ca²⁺ pumps, which results in increased intracellular calcium and cell necrosis.

**MEDICATIONS**

Drugs in almost every category have been implicated as a cause of rhabdomyolysis. The medications of most concern are the lipid-lowering agents, including 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (lovastatin, simvastatin) and fibric acid derivates that decrease triglyceride synthesis (gemfibrozil and clofibrate). HMG-CoA reductase inhibitors block the production of coenzyme Q, which plays an important role in the production of ATP in mitochondria. The resultant decrease in ATP production leads to cell death and subsequent rhabdomyolysis. Patients with preexisting renal dysfunction are at increased risk.

Immediate withdrawal of these drugs is mandatory if patients complain of muscle dysfunction or if their CK level rises to more than three times normal. The risk for drug-induced muscle disease is aggravated by the simultaneous administration of danazol, nicotinic acid, cyclosporine, itraconazole, or erythromycin. The combination of HMG-CoA reductase inhibitors with gemfibrozil also carries a high rate of myotoxicity.

**DRUGS OF ABUSE**

Substance abuse is one of the most common causes of rhabdomyolysis, largely because of the high incidence of ethanol abuse and its direct toxicity to the myocyte membrane. Other drugs of abuse implicated in cases of rhabdomyolysis include cocaine, heroin, methamphetamine, phencyclidine hydrochloride (PCP), lysergic acid diethylamide (LSD), 3,4-methylenedioxymethamphetamine (MDMA; “ecstasy”), benzodiazepines, and barbiturates. Most abused drugs cause muscle damage through direct toxic effects or immunologic reactions to the contaminants found mixed with the drug. Cocaine is also toxic to the sarcolemma and induces vasospasm resulting in ischemia. Cocaine increases energy demands of the cell that outstrip energy production.

Besides its direct toxicity, ethanol has multiple additional mechanisms by which it causes muscle damage. Its sedative and hypnotic properties may cause prolonged immobilization of a body part, with external compression of its blood supply leading to ischemia. Rhabdomyolysis can be induced by excessive motor activity when associated with alcohol-related seizures and delirium tremens. Poor nutrition inhibits the rate of ethanol metabolism, and the resultant higher blood ethanol concentration at the cell membrane for prolonged periods leads to increased sarcolemmal damage.

**TOXINS**

Toxins that cause direct myocyte damage include venom from the European adder, the Australian tiger snake, the Australian king brown snake, the death adder, and North and South American rattlesnakes. These snakes deploy a single venom with multiple myocyte toxins that cause direct muscle injury and rhabdomyolysis. Stings from Africanized bees (killer bees) and honeybees mediate rhabdomyolysis through myotoxins. Quail fed hellebores or hemlock have also been associated with outbreaks of rhabdomyolysis (coturnism). Outbreaks of Haff disease occur intermittently in the United States as a result of contaminated fish.

Toxins that act at the molecular level by interfering with the production of ATP are capable of producing damage to skeletal muscle. Carbon monoxide, cyanide, hydrogen sulfide, and phosphine inhibit electron transport in mitochondria; salicylates and chlorphenoxyl herbicides uncouple oxidative phosphorylation; and iodoacetate and sodium fluorooacetate inhibit glycolysis in the Krebs cycle.

**GENETIC DISORDERS**

Rhabdomyolysis can result from genetic defects in glycolysis, glycogenolysis, fatty acid oxidation, and mitochondrial function. These disorders cause inappropriate use of carbohydrate and lipids, which leads to an imbalance between energy supply and demand in myocytes.

Genetic defects should be suspected in patients in whom the cause of rhabdomyolysis is obscure. Symptoms often begin before the age of 20 years, and attacks occur intermittently. Examples include recurrent rhabdomyolysis after minimum to moderate exercise, after viral infections starting in childhood, or in patients with a family history of rhabdomyolysis. In glycogenolytic disorders, the mode of inheritance is usually autosomal dominant; phosphoglycerate kinase deficiency is X-linked.

Diagnosis of an inherited muscle enzyme defect is based on muscle biopsy findings demonstrating abnormally increased glycogen or lipid deposits, as well as histochemical staining demonstrating a decrease or absence of specific enzymes.

**PRESENTING SIGNS AND SYMPTOMS**

Common symptoms include myalgias, fatigue, and red or brown urine; however, atypical findings are customary for rhabdomyolysis. Only 50% of patients complain of specific muscle symptoms, and less than 10% have muscle tenderness. Liberal testing for rhabdomyolysis is therefore warranted in high-risk populations. Rhabdomyolysis should be considered in patients with hyperkalemia, disseminated intravascular coagulation (DIC), sepsis, cardiovascular collapse, compartment syndrome, heat stroke, altered mental status, and acute kidney injury. These patients may have occult primary rhabdomyolysis or suffer from rhabdomyolysis as a complication of their primary disease process.

**CREATINE KINASE**

CK is the enzyme responsible for reversible transfer of the terminal phosphate group of ATP to creatine to form phosphocreatine. Serum CK begins to rise 2 to 12 hours after the destruction of more than 200 g of muscle, with the peak level occurring between 1 and 3 days. Levels decline within 3 to 5 days after the muscle injury ceases. Serum CK levels remain elevated longer than those of myoglobin because of relatively slow plasma clearance (serum t½ = 1.5 days). CK decreases at a steady rate of 39% per day. Rhabdomyolysis is
suspected at minimum thresholds for CK of between 1000 and 10,000 U/L.

A rise in serum CK follows the rise in serum myoglobin. Three isoenzymes of CK exist in human tissues: MM, MB, and BB. The predominant source of the CK-MM isoenzyme is skeletal and cardiac muscle; CK-BB is found in brain tissue and CK-MB mainly in cardiac muscle. In rhabdomyolysis, the primary CK isoenzyme elevated is CK-MM. Creatine phosphokinase is a serum marker of CK-MM reported by many clinical laboratories.

**MYOglobin**

Myoglobin is a small protein with a free circulating concentration that is very low under normal physiologic conditions. Myoglobin functions as an oxygen reservoir in muscles; serum myoglobin levels rise within 1 hour of skeletal muscle damage. Myoglobin levels become normal within 1 to 6 hours after the cessation of muscle injury because of rapid clearing both by renal excretion and by metabolism to bilirubin.

When myoglobin levels reach 15 mg/L, it can be detected by urine dipstick, and at 1 g/L it may cause the color of urine to appear dark, like cola. Myoglobinuria does not always result in dark urine, however; discoloration depends on (1) the amount of myoglobin released from muscle into plasma, (2) the glomerular filtration rate, and (3) the urine concentration.

**URINALYSIS**

The urine dipstick is a commonly used screening test for rhabdomyolysis. The orthotoluidine test on the urine dipstick will react in the presence of either myoglobin or hemoglobin. A report of “large blood” on the urine dipstick and absence of red blood cells on microscopy classically suggests the presence of free myoglobin in urine. Figure 169.1 shows the typical urine appearance in the setting of myoglobinuria. Unfortunately, clinical data do not fully support this screening practice, with microscopic hematuria occurring in about 30% of patients with rhabdomyolysis. In addition, myoglobinuria may be transient and not identified at the time of urinalysis despite the presence of significant clinical rhabdomyolysis. Dipstick testing will detect a urine myoglobin level higher than 1.0 mg/dL, which correlates with a serum value of approximately 100 mg/dL.

Other common findings on urinalysis include the presence of tubular casts, proteinuria, and evidence of acute tubular necrosis.

**RENAI LN FUNCTION TESTS**

Though not consistently observed in all analyses, creatinine has at times been shown to rise faster with rhabdomyolysis than with other causes of acute renal failure. Markedly high creatinine levels or a relatively low ratio of blood urea nitrogen to creatinine should raise suspicion for rhabdomyolysis (Box 169.3).

**COMPLICATIONS**

Following sufficient muscle damage, extrusion of cellular contents into the general circulation causes several complications, including acute renal failure, metabolic derangements, DIC, compartment syndrome, and peripheral neuropathy.

**METABOLIC AND ELECTROLYTE DERANGEMENTS**

Hyperkalemia occurs in 10% to 40% of patients with rhabdomyolysis. It is the most serious electrolyte derangement.
are usually asymptomatic. Hypocalcemia results from deposition of calcium salts in necrotic muscle secondary to hypophosphatemia and decreased 1,25-dihydroxycholecalciferol. Soft tissue calcifications can be seen on radiographs of the involved limbs. Hypocalcemia should be treated only if severe symptoms or hypokalemia develops and leads to cardiac arrhythmias, muscular contraction, and seizures. Later, as calcium is mobilized from tissues, serum calcium levels rise and symptomatic hypercalcemia may develop. Hypercalcemia usually occurs in patients with acute renal failure during the diuretic phase, typically when urinary output is greater than 1500 mL/24 hr. Hypercalcemia also occurs more frequently if Ca\(^{2+}\) is supplemented in the hypocalcemic stage. Volume expansion alone is usually adequate treatment, but diuretics may be needed.

Hyperphosphatemia is caused by leakage of phosphate from injured myocytes and is higher in azotemic patients. Phosphate binders should be used when phosphate levels exceed 7 mg/dL. Hypophosphatemia may be seen later in the disease course but rarely requires treatment. Hypermagnesemia may occur in patients with renal insufficiency. Standard management is appropriate. Hyperuricemia is especially common in crush injury as a result of the release of muscle adenosine nucleotides, which are subsequently converted to uric acid in the liver. Uric acid levels typically correlate with serum CK levels.

Organic acids, especially lactic acid, are released from hypoxic, necrotic muscle cells and produce a pronounced anion gap acidosis.

**COMPARTMENT SYNDROME**

Most striated muscles are contained within rigid compartments formed by fascia and bones. When the muscle is traumatized, marked swelling and edema occur within a closed osteofascial compartment, and muscle perfusion is reduced to a level below that required for cellular viability. As intracompartmental pressure rises above 30 to 35 mm Hg, compartment syndrome develops and significant muscle ischemia ensues and requires decompressive fasciotomy. Figure 169.2 shows an example of compartment syndrome.

Classic signs and symptoms of compartment syndrome include pain, pallor, paresthesias, poikilothermia, paralysis, and pulselessness. Paresthesias are the most reliable sign—muscle edema exerts pressure on peripheral nerves, which results in neuronal ischemia, paresthesias, and paralysis. Decompressive fasciotomy reverses the peripheral neuropathies within a few days to weeks, although symptoms may be permanent in a minority of patients.

**DISSEMINATED INTRAVASCULAR COAGULATION**

DIC occurs in patients with severe rhabdomyolysis when extensive injury results in multisystem organ failure. Although this disorder is more common with severe trauma and crush injury, rhabdomyolysis from medical causes may lead to DIC. Severe bleeding is most pronounced on days 3 to 5 of illness. If severe bleeding does not occur, spontaneous improvement can be expected by days 10 to 14. When severe bleeding does occur, infusion of fresh frozen plasma (to replace coagulation factors) and transfusion of platelets may be indicated.
Compartment syndrome. This man was in coma from a heroin overdose and had been lying on his arm for a number of hours. He was hypotensive, in renal failure, comatose, and on a ventilator. The entire arm was swollen and rhabdomyolysis was suspected correctly. Because of the coma, he was unable to voice any complaint of pain. When he awakened 20 hours later, the pain was severe, and measurement of compartment pressure demonstrated the need for fasciotomy. Heroin can cause rhabdomyolysis and hypotension on reperfusion, and certainly prolonged pressure on the muscles may have exacerbated the condition. (From Roberts JR, Hedges JR. Clinical procedures in emergency medicine. 5th ed. Copyright 2009 Saunders, an imprint of Elsevier.)

HEPATIC DYSFUNCTION
Hepatic dysfunction occurs in approximately 25% of patients with rhabdomyolysis. The proteases released from injured muscle may be implicated in hepatic inflammation.

TREATMENT

GENERAL MEASURES
Rhabdomyolysis is physiologically and clinically similar to cell degradation states such as tumor lysis syndrome and sepsis. An organized, aggressive treatment strategy should focus on clinical end points similar to those for other cell lysis conditions. The emergency treatment of rhabdomyolysis, in an early goal-directed fashion, is summarized in Figure 169.3.

The main goal of therapy is prevention of acute renal failure through high-volume resuscitation. The two most common reasons for the development of acute kidney injury are slow fluid resuscitation and inadequate fluid resuscitation. Normal saline is superior to lactated Ringer solution for the treatment of rhabdomyolysis because normal saline is not associated with risk for phosphate toxicity. More than 10 L of normal saline is typically administered in the first 24 hours of therapy to maintain high-volume dilute urine output.

Initial fluid administration with normal saline is titrated to achieve a goal urine output of 200 to 300 mL/hr. It is important that intravenous (IV) fluid resuscitation be started as soon as possible; fluid resuscitation before the extrication of crushed and trapped patients is preferred. After diuresis is established and urine pH is less than 6.5, fluids are changed to a more alkaline solution (i.e., 75 mmol of sodium bicarbonate added to 1 L of one-half isotonic saline), with the rate titrated to achieve the goal of 200 to 300 mL/hr of urine output. Alternating normal saline with sodium bicarbonate is also an option. If urine pH is higher than 6.5, normal saline is continued. Mannitol, an osmotic diuretic, can be considered in this situation, but only after adequate fluid repletion has been attained.

With moderate to severe alkalemia (serum pH higher than 7.5), acetazolamide can be considered. The goal urine output remains 200 to 300 mL/hr. Fluid repletion is continued until the CK level falls below 5000 to 10,000 U/L and the myoglobinuria clears.

If initial diuresis is not achieved with fluid replacement alone or the patient has contraindications to further fluid replacement, additional diuretics should be considered and a nephrologist consulted for possible renal replacement therapy.

Vital signs, cardiac rhythm, and urine output should be monitored continuously. Medication dosages should be adjusted according to renal function, and drugs that are potentially nephrotoxic should be avoided.

PHARMACOLOGIC THERAPY

Mannitol
Mannitol theoretically exhibits several protective mechanisms. It is a potent diuretic that may increase myoglobin solubility and excretion in the renal tubules, thereby reducing cast formation. It decreases sodium reabsorption in the kidney, which may promote renal conservation by decreasing the energy requirement of the renal medulla. Additionally, mannitol is probably a potent oxygen free radical scavenger. Mannitol also improves compartment pressures in compartment syndromes that result from crush injuries.

The available literature regarding the effectiveness of mannitol in preventing kidney injury from heme pigment is conflicting. No randomized, controlled trial has supported the general use of mannitol for rhabdomyolysis. However, limited evidence suggests that mannitol along with sodium bicarbonate may be beneficial when CK levels are higher than 20,000 to 30,000 U/L.

Mannitol therapy can be given in both an intermittent and continuous fashion. Intermittent therapy is preferred, with a dose of 0.5 to 1 g/kg (averaged as 400 g over a 60-hour
Entry criteria for EGDT for rhabdomyolysis:

Absolute CK value of >15,000
or
CK > 5000 AND ANY of:
1. Associated crush injury
2. Acute renal failure or injury
3. Myoglobinuria
4. Associated acidosis, hypocalcemia, or hyperkalemia
5. Massive muscle injury
6. Prolonged extraction or delayed arrival >4 hr

Large bore, IV access, baseline labs
Cardiac monitors, ECG
Urinary (Foley) catheter
Initial resuscitation 1-2 L of 0.9% NS

Is there urine output (at least 30 mL/hr)?
YES NO

Check urine pH

Measure CVP

CVP < 6 cm H₂O
• 1-2 L @ 15–30 min until either:
  - UOP or
  - Pulmonary edema

CVP > 6 cm H₂O
• Consider furosemide
• Early nephrology consult for RRT
• Continue 1-2 L @ hour until:
  - UOP or
  - Pulmonary edema

D₅NL bicarb 1-L boluses
@ 15-30 min

Recheck urine pH
Check serum pH

Urine pH 6.5
Serum pH < 7.5
Continue D₅NL bicarb
bolus and reassess

Urine pH 6.5
Serum pH > 7.5
Continue NS boluses
Consider mannitol

Urine pH 6.5
Serum pH ≥ 7.5
Continue NS Start mannitol
Consider acetazolamide

Urine pH 6.5
Serum pH < 7.5
Continue NS
Consider acetazolamide

Correct metabolic derangements

Admit, disposition

Achieve urine output of 200-300 mL/hr?
YES NO
↓ IVF to maintain UOP 200-300 mL/hr

Continue as above and consider nephrology consult for RRT

Fig. 169.3 Early goal-directed therapy for rhabdomyolysis. CK, Creatine kinase; CVP, central venous pressure; D₅NL bicarb, 5% dextrose in normal sodium bicarbonate solution; EGDT, early goal-directed therapy; IV, intravenous; IVF, intravenous fluid; NS, normal saline; RRT, renal replacement therapy; UOP, urinary output.
period) to achieve a urine output of 300 mL/hr. Serum sodium and osmolarity should be checked frequently to avoid a hyper-osmolar state. Acute kidney injury is more likely to occur with doses higher than 200 g/day and a cumulative dose higher than 800 g.

**Sodium Bicarbonate**

Patients with idiopathic rhabdomyolysis may not need bicarbonate therapy, but severely injured or hypotensive patients generate a tremendous organic acid load that often requires treatment with supplemental sodium bicarbonate. Bicarbonate infusion of more than 500 mEq in 24 hours may be indicated. Urine alkalization with sodium bicarbonate potentially reduces heme protein precipitation and cast formation. As with mannitol, no randomized, controlled trials have demonstrated that sodium bicarbonate therapy is more effective than normal saline alone. Caution should be exercised when administering large doses of bicarbonate because treatment may exacerbate hypocalcemia, alkalalemia, and related arrhythmias.

**Acetazolamide**

Acetazolamide prevents the complications of serum alkalalemia caused by bicarbonate therapy. It promotes the excretion of sodium bicarbonate in the renal tubules, thereby inhibiting cast formation. When serum pH exceeds 7.50, a standard dose of acetazolamide (250 mg) may be administered.

**RENA L REPLACEMENT THERAPY AND HEMODIALYSIS**

Early hemodialysis is not necessary unless crush injuries or certain complications have occurred (e.g., severe hyperakalemia, refractory metabolic acidosis, oliguria or anuria, volume overload). Early consultation with a nephrologist is warranted. Myoglobin molecules can be removed by hemofiltration, but not by hemodialysis or peritoneal dialysis.

Reductions in morbidity and mortality have been observed in victims of mass casualty incidents who underwent dialysis within 4 to 6 hours of injury.

**EXPERIMENTAL THERAPY**

Several promising experimental therapies for rhabdomyolysis have been studied in animal models but have not been well tested in humans. Nitric oxide may prevent acute renal failure by promoting renal vasodilation, and lazaroïds (21-aminosteroids) inhibit oxidant-induced lipid peroxidation in animals. Other experimental treatment modalities include deferoxamine (an iron chelator), glutathione, vitamin E, carvedilol, and dantrolene.

**AVOID CALCIUM SUPPLEMENTATION AND LOOP DIURETICS**

Patients with rhabdomyolysis often have acute hypocalcemia. The hypocalcemia results from deposition of calcium salts in necrotic muscle. Supplemental calcium administration should be avoided if possible because it can exacerbate the cytoplasmic injury. During the rebound and recovery phases of rhabdomyolysis, calcium is remobilized and hypercalcemia becomes a true risk. Only if the patient is symptomatic or if severe hyperkalemia is present should calcium be considered, and even then other measures to ameliorate the hyperkalemia should be undertaken first.

Loop diuretics (e.g., furosemide) should generally be avoided because they contribute to urine acidification and tubular cast formation. Forced diuresis is best facilitated with mannitol. Under alkalemic conditions, acetazolamide can be considered.

**Cautions for a Physician**

Hypercalcemia can develop after recovery of acute renal failure secondary to rhabdomyolysis. Calcium administration should be avoided during renal failure unless the patient has symptomatic hypocalcemia or severe hyperkalemia.

With the large volume of fluid administration typically needed in patients with rhabdomyolysis, it is important to monitor the patient closely for any evidence of fluid overload. If mannitol is used, serum sodium and osmolarity should be checked frequently to avoid a hyperosmolar state. Acute kidney injury may occur with doses higher than 200 g/day and cumulative doses higher than 800 g. If alkalization of urine is initiated, there is a potential for worsening of hypocalcemia. It can also lead to hypokalemia. Urine pH, serum bicarbonate, serum calcium, and serum potassium should be monitored, and if urine pH does not rise after 4 to 6 hours or if symptomatic hypocalcemia develops, alkalinization should be stopped.

**CRUSH SYNDROME: DISASTER AND MASS CASUALTY CONSIDERATIONS**

Delayed extrication from debris causes delayed resuscitation—rhabdomyolysis and crush syndrome often emerge as the leading causes of delayed mortality. Crush syndrome, perhaps the most dramatic manifestation of rhabdomyolysis, results from both the initial blunt force trauma and the marked reperfusion injury that occurs after release of the crushing pressure. Commonly, crush syndrome will occur epidemically because of structural failure from earthquakes or warfare with resultant entrapment of victims beneath debris. Although acute renal failure is the most life-threatening manifestation, crush syndrome can occur with failure of any organ system, much like rhabdomyolysis. Frequently, management of the obvious concomitant traumatic injuries can overshadow the emergency of crush syndrome.

Crush syndrome and compartment syndrome act synergistically on the degradation of muscle. Acute musculoskeletal compartment syndrome can damage myocytes and induce rhabdomyolysis. Rhabdomyolysis in turn exacerbates the inflammatory cascade associated with crushing of the muscle compartment, thereby worsening compartment pressures. Crush syndrome may worsen acute renal failure.

During mass casualty situations in which crush injuries would be expected (earthquakes, building collapse, bombings), it is important to start IV volume restoration in all survivors as quickly as possible (see the Tips and Tricks box “Management of Crush Syndrome”). Emergency medical service and ED personnel should be instructed to begin IV...
resuscitation even before the victims have actually been extricated from the scene. This may involve placing an IV line in a confined space on any free limb.

The International Society of Nephrology can be contacted to respond to a mass casualty incident with emergency renal therapy equipment through its Disaster Relief Task Force (http://www.isn-online.org/isn/society/about/isn_20011.html).

**SUGICAL THERAPY**

Surgical therapy is a consideration for patients with rhabdomyolysis caused by crush syndrome. Amputation removes damaged muscle that serves as the source of cellular toxins.

Physiologic amputation can act as temporizing measure when immediate surgical care is not available, particularly in the setting of disasters or military combat. To perform physiologic amputation, one or two tourniquets are applied firmly to the extremity above the level of injury or entrapment, and dry ice is applied distal to the tourniquet. Combat surgery hospitals beginning in World War II through current conflicts have performed this procedure with success. Physiologic amputation rapidly reduces myoglobin and other intracellular toxins associated with crushed, ischemic, or septic extremities. This can dramatically reduce myoglobinuria and reperfusion injury. Physiologic tourniquets have allowed definitive surgery to be delayed for up to 32 days. Emergency physicians must be aware, however, that physiologic amputation will inevitably result in loss of the affected limb.

Early prophylactic fasciotomy increases the need for transfusions and the risk for both sepsis and death. Fasciotomy is not indicated unless signs of compartment syndrome are observed.5

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Most patients with rhabdomyolysis should be admitted to a telemetry floor staffed by a physician or to an intensive care unit. If there is uncertainty regarding the diagnosis or severity, patients should be admitted for observation, testing, and treatment.

Rhabdomyolysis can be associated with acute kidney injury. Patients with renal failure should be admitted to the hospital and a nephrologist consulted early in the treatment course.

Patients with minimal elevations in CK and no identifiable complications may be managed as an outpatient if urgent follow-up with a primary care provider can be ensured.

Pituitary Apoplexy

Brian K. Nelson

The posterior lobe is an extension of the hypothalamus and secretes two hormones: antidiuretic hormone (or arginine vasopressin) and oxytocin. The pituitary stalk and the portal vessel pass through a small diaphragm that separates the sella turcica from the middle fossa. This anatomic arrangement places the pituitary at risk for infarction or hemorrhage when a mass increases pressure in the sella or compresses the stalk and vessels. Higher intrasellar pressures are associated with poor outcomes.

Pituitary tumors are common and many are asymptomatic. They are classified by size (microadenoma, <10 mm; macroadenoma, >10 mm) and by the hormone produced. Of tumors that cause clinical symptoms, the most commonly secreted hormones are PRL, which leads to hypogonadism; GH, which promotes acromegaly; and ACTH, a cause of Cushing disease.

Tumors involved in apoplexy are typically nonfunctional and unsuspected macroadenomas. In patients undergoing an endocrine stimulation test for hypogonadism, hypothyroidism, or adrenal insufficiency, apoplexy may occasionally develop secondary to stimulation of a macroadenoma. Treatment of a pituitary tumor can also precipitate apoplexy, particularly in cases of surgery, irradiation, or bromocriptine administration. Other reported risk factors include pregnancy (Sheehan syndrome), head trauma, recent cardiac surgery, anticoagulation, hypertension, diabetic ketoacidosis, and ovarian stimulation medications.5

Most patients with pituitary apoplexy have no identifiable risk factor. Apoplexy may occur in normal glands.

KEY POINTS

- Pituitary apoplexy is a rare but serious condition caused by hemorrhage or infarction of the pituitary gland.
- Patients are seen acutely with severe headache, meningeal irritation, visual field deficits, cranial nerve palsies, loss of visual acuity, and altered mental status.
- Acute hypopituitarism may develop following pituitary apoplexy. Treatment of impending adrenal crisis is mandatory.
- Emergency consultation with a neurosurgeon who has expertise in pituitary surgery and management is required.

EPIDEMIOLOGY

Pituitary adenomas are common, with a prevalence of 3% to 27% in various autopsy series. They are rarely diagnosed in life, with a reported incidence of 4 per 100,000 in a Finnish population and a prevalence of 77 per 100,000 in a British one.1,2 Apoplexy occurs in a minority of such lesions and can occasionally be seen with normal glands. Because of the relative rarity of this condition, pituitary apoplexy may be confused with more common entities such as subarachnoid hemorrhage. Delay in diagnosis and treatment may lead to blindness, permanent cranial nerve palsies, or death.1,4

PATHOPHYSIOLOGY

The two lobes of the pituitary gland sit within an enclosed space known as the sella turcica. Blood supply to this gland is one of the richest of all mammalian tissues.

The anterior lobe receives the portal hypophyseal vessel from the hypothalamus. Differentiated cells in the anterior lobe secrete specific hormones, including growth hormone (GH), adrenocorticotropic hormone (ACTH), prolactin (PRL), thyroid-stimulating hormone (TSH), and gonadotropins: luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

The findings in patients with pituitary apoplexy vary from mild headache to sudden collapse and coma. Most patients exhibit severe frontal or retroorbital headache, vomiting, impaired visual acuity, visual field defects, hypopituitarism, and subsequent adrenal crisis. A minority have ocular palsies, obtundation, meningeal irritation, blindness, or long-tract signs. The visual field deficit is classically bitemporal upper quadrantanopia or hemianopia. Associated cerebral infarction occasionally occurs secondary to vasospasm from subarachnoid hemorrhage or direct compression of the internal carotid artery by tumor. Table 170.1 lists the frequency of signs and symptoms reported in four case series.3,5,7
VARIATIONS

Hypopituitarism

Most cases of hypopituitarism are diagnosed in the outpatient setting because of their subacute or indolent manifestation. Patients with hypopituitarism exhibit sequential signs and symptoms of GH deficiency, hypogonadism, hypothyroidism, and adrenal insufficiency. They are typically weak, hypopigmented, and overweight and appear chronically ill. Body hair and genitalia are diminished. Severe cases may be complicated by bradycardia and hypotension.

Asymptomatic Pituitary Tumors

Silent tumors are incidental microadenomas found during imaging studies ordered for an unrelated condition. Patients with silent tumors have no symptoms attributable to cell type.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Common neurologic emergencies can be confused with pituitary apoplexy (Box 170.1). The sudden onset of severe headache suggests subarachnoid hemorrhage. Obundation and meningeal signs suggest meningitis, cerebral hemorrhage, or cerebral venous thrombosis. Cranial nerve findings in the setting of altered mental status may indicate cavernous sinus thrombosis or midbrain infarction. Rare hypothalamic and pituitary compressive or destructive processes may closely mimic apoplexy because of accompanying headaches and visual field deficits. Two such mimics are lymphocytic hypophysitis and Rathke cleft cysts. Pediatric craniopharyngiomas and several primary and metastatic lesions in adults may also compress the pituitary gland and mimic apoplexy. Generally, deficits in visual acuity and visual fields raise suspicion for apoplexy in the appropriate clinical setting.

BOX 170.1 Differential Diagnosis

Sudden severe headache with or without changes in mental status or long-tract signs
- Subarachnoid hemorrhage, meningitis, cerebral hemorrhage, mass, infarction, intracranial venous thrombosis
- Severe headache with decreased visual acuity, ocular palsies, or visual field changes
- Complicated migraine, cavernous sinus thrombosis, cerebellar hemorrhage, midbrain infarction
- Signs of hypogonadism, hypoadrenalism, or hypothyroidism
- Causes of hypopituitarism, including remote head injury, lymphocytic hypophysitis, iatrogenic surgical or radiation injury, and infections (particularly tuberculosis and mycotic infections); consider primary hypoadrenalism and hypothyroidism

RED FLAGS

The following signal the need for immediate surgical decompression:
- Changes in mental status
- Rapidly progressive course
- Severe vision loss

DIAGNOSTIC TESTING

Visual acuity and confrontational visual field testing should be performed when the diagnosis of pituitary apoplexy is considered. Samples should be obtained for electrolytes, renal function, liver function, clotting screen, blood counts, random cortisol, thyroxine, TSH, PRL, insulin-like growth factor, GH, LH, FSH, and testosterone in men and estradiol in women. A non–contrast-enhanced computed tomography scan of the head will exclude the diagnosis of acute subarachnoid hemorrhage. Endocrine simulation testing could worsen the condition and should be deferred. Computed tomography is not sufficiently sensitive to exclude a pituitary process. Contrast-enhanced, diffusion-weighted magnetic resonance imaging allows the best visualization of pituitary tumors and details of the hemorrhage and infarction within them (Fig. 170.1, A and B).

MANAGEMENT

Parenteral hydrocortisone (100 mg every 6 hours) or dexamethasone (4 mg every 12 hours) is given to decrease tumor edema and treat impending adrenal crisis. Obtunded or comatose patients should be intubated.

There is controversy regarding conservative treatment with steroids versus surgical intervention. Patients with minimal or improving visual symptoms are sometimes managed medically. Definitive treatment is pituitary decompression, most often through a transsphenoidal approach. The outcome depends on the severity of symptoms at initial
CHAPTER 170  PITUITARY APOPLEXY

PRIORITY ACTIONS

Do:
- Fingerstick glucose test; treat if hypoglycemic.
- Draw blood for serum cortisol, thyroid-stimulating hormone, and free $T_4$ (thyroxine).
- Administer parenteral hydrocortisone, 100 mg four times daily, or dexamethasone, 4 mg twice daily.
- Provide fluid and electrolyte support.
- Perform computed tomography to exclude subarachnoid hemorrhage, followed by magnetic resonance imaging.
- Initiate early consultation with an endocrinologist and neurosurgeon with pituitary expertise.
- Admit the patient to a neurologic critical care unit.

Do Not:
- Withhold glucocorticoids while awaiting laboratory results.
- Attempt endocrine simulation testing in the emergency department.

DOCUMENTATION

Onset, location, and severity of the headache
Mental status
Complete neurologic examination, including visual acuity and confrontational visual fields
Initial glucose, electrolytes, volume status
Results of initial imaging studies

Patients with subacute or chronic panhypopituitarism should be evaluated by an endocrinologist for initiation of therapy and further management. Asymptomatic pituitary tumors can be safely followed in the outpatient setting because such cases rarely progress to apoplexy.

Meningitis, Encephalitis, and Brain Abscess
Amandeep Singh and Susan B. Promes

KEY POINTS

- There is significant overlap among the initial clinical presentations of meningitis, encephalitis, and brain abscess.
- The four most common bacteria responsible for adult bacterial meningitis are Streptococcus pneumoniae, Neisseria meningitides, Haemophilus influenzae type B, and Listeria monocytogenes. Group B Streptococcus remains the predominate cause of meningitis in infants less than 2 months of age.
- The classic constellation of fever, neck stiffness, headache, and change in mental status are seen in less than 50% of cases of acute bacterial meningitis.
- Cranial computed tomography (CT) scan, prior to lumbar puncture, is recommended in patients with a history of immunocompromised state, history of central nervous system (CNS) disease, new-onset seizure, abnormal neurologic examination, papilledema, altered mental status, or altered level of consciousness.
- Empiric therapy in patients with high clinical suspicion for CNS infection should not be delayed for neuroimaging or lumbar puncture.
- Although epidemiologic clues and assessment of risk factors should be sought in all patients with encephalitis, herpes simplex virus and arboviruses remain the most common causes of nonepidemic and epidemic outbreaks of encephalitis, respectively, in the United States.
- Acyclovir should be initiated in all patients with suspected encephalitis, pending the results of diagnostic studies.
- Risk factors for the development of intracranial abscess include inadequately treated subacute or chronic ear, nose, mastoid, and dental infection; endocarditis; congenital heart disease; and having undergone neurosurgical procedures.
- Patients with intracranial abscess often present with mild headache symptoms in the weeks to months prior the emergency department visit. The classic triad of fever, headache, and focal neurologic deficit is seen in less than 20% of patients with brain abscess.

MENINGITIS

EPIDEMIOLOGY

The combination of routine vaccination against Streptococcus pneumoniae, Haemophilus influenzae type B, and Neisseria meningitides, maternal screening for and intrapartum treatment of group B Streptococcus (Streptococcus agalactiae), and enhanced efforts to reduce the contamination of processed foods by Listeria monocytogenes have all led to a significant decrease in the incidence of acute bacterial meningitis (ABM). Data from the Emerging Infections Programs Network, established by the Centers for Disease Control and Prevention (CDC), have noted a decrease in the incidence of meningitis from 2.0 cases per 100,000 population in 1998 to 1999 to 1.38 cases per 100,000 population in 2006 to 2007.1 During this same time the case fatality rate decreased to 14.3%. Projecting these data on a national level reveals an estimated 4100 cases and 500 deaths from bacterial meningitis annually in the United States.1

ETIOLOGY

A 10-year review (1998 to 2007) of 3188 cases of bacterial meningitis noted that S. pneumoniae accounted for the greatest proportion of cases (58%), followed by group B Streptococcus (18.1%), N. meningitides (13.9%), H. influenzae (6.7%), and L. monocytogenes (3.4%).1 Among infants less than 3 months of age, group B Streptococcus and gram-negative rods account for most cases of ABM. After 3 months of age, S. pneumoniae and N. meningitidis become the predominate pathogens. L. monocytogenes is primarily seen in infants less than 1 month of age, in adults more than 50 years old, and in immunocompromised patients. Staphylococcus aureus is acquired mainly nosocomially and occurs
PATHOPHYSIOLOGY

ABM develops after encapsulated bacteria, which have colonized the nasopharynx and/or oropharynx, penetrate the intravascular space and enter the subarachnoid space through vulnerable sites within the blood-brain barrier. Once the pathogens enter the central nervous system (CNS), they replicate rapidly, thus consuming glucose and liberating protein within the cerebrospinal fluid (CSF). The ensuing inflammatory reaction occurs in response to the liberation of bacterial cell wall and cell membrane components (e.g., lipopolysaccharide, peptidoglycan, lipoteichoic acid) and the induction of proinflammatory mediators. These events culminate in injury to the vascular endothelium that results in increased vascular permeability to the blood-brain barrier, meningeal inflammation, and cerebral vasculitis. The accompanying cerebral edema and increase in intracranial pressure (ICP) contribute to CNS hypoperfusion and cell death.

Other routes of pathogen entry include direct inoculation of the CNS, seen in trauma or surgery, through direct infection and seeding of parameningeal structures (e.g., from endocarditis or concurrent infection), contact and aspiration of maternal intestinal and genital tract secretions during birth.

PRESENTING SIGNS AND SYMPTOMS

Patients with ABM typically appear ill and often present within 24 to 72 hours of symptom onset. Table 171.1 reviews the presenting signs and symptoms of adults with ABM. The cardinal symptoms of ABM (i.e., fever, neck stiffness, change in mental status, and headache) are seen in combination in less than half of all patients. Nearly 95% of patients will present with at least two of these cardinal symptoms, which provides the rationale for performing a lumbar puncture in patients who are lethargic or confused and develop a fever.

The absence of these four findings typically excludes the diagnosis of ABM.

The headache described by patients with ABM can be moderate to severe in intensity, generalized, often with an occipital or nuchal component, and unlike “normal” headaches. Photophobia is commonly present, as is nausea. Worsening of the headache while the examiner rapidly turns the patient’s head from side to side (at a rate of two to three times per second), the so-called jolt accentuation test, has been reported to be helpful in identifying patients with ABM, but a recent study questioned the utility of this finding.

Although neck pain may be infrequently reported, the objective finding of neck stiffness is seen in more than 80% of patients. Examining the neck for rigidity, during gentle forward flexion, with the patient in the supine position best assesses neck stiffness, whereas difficulty in lateral motion of the neck is a less reliable finding. Patients with severe meningeal irritation may spontaneously assume the tripod position (also called the Amoss sign or the Hoyne sign) with the knees and hips flexed, the back arched lordotically, the neck extended, and the arms brought back to support the thorax. The Kernig sign is performed with the patient lying supine and the hip and knee flexed to 90 degrees. A positive sign is present when extension of the knee from this position elicits resistance or pain in the lower back or posterior thigh. The classic Brudzinski sign refers to spontaneous flexion of the knees and hips during attempted passive flexion of the neck. A separate sign described by Brudzinski, the contralateral reflex, is present if passive flexion of one hip and knee causes flexion of the contralateral leg. The presence or absence of Kernig or Brudzinski signs has been shown to have little positive or negative predictive value in the diagnosis of ABM, unless severe meningeal inflammation is present.

Atypical presentations of ABM occur in infants, older adults, and immunocompromised patients. Infants with bacterial meningitis may present with fever or hypothermia, hypoglycemia, poor feeding, seizures, or irritability (excessive or abnormal crying). On examination, the findings of jaundice, ill appearance, a bulging fontanelle, meningeal irritation (including neck stiffness, the Kernig sign, and the Brudzinski sign), fever higher than 40°C, and increased general body tone predict bacterial meningitis.

Older and immunocompromised patients may also present atypically. These populations are associated with a higher rate of misdiagnosis that contributes to an increase in the morbidity and mortality following an episode of acute meningitis. A lower proportion of fever, headache, and nausea or vomiting is present in these subgroups. Neck stiffness has a lower sensitivity and specificity for meningitis in older patients. Finally, these populations may present to the emergency department (ED) with altered mental status and/or altered level of consciousness but without a fever.
The differential diagnosis of patients presenting with fever, headache, and altered mental status includes other forms of meningitis (e.g., nosocomial meningitis, aseptic meningitis), encephalitis, and cerebral abscess. The diagnosis of meningitis is challenging in patients who present atypically. In a review of 156 cases of meningitis in patients who presented to a single tertiary care hospital, 66 cases were initially misdiagnosed in the ED as an alternative infection (i.e., sepsis of unclear origin, pneumonia, urinary tract infection), metabolic encephalopathy, or nonspecific conditions (e.g., weakness, malaise, degenerative state). Higher percentages of these patients were more than 65 years of age, and these patients were also noted to have lower proportions of fever, headache, nausea or vomiting, and neck stiffness.10

Nosocomial meningitis may result from invasive CNS procedures (e.g., craniotomy, placement of ventricular catheters, lumbar puncture [LP], intrathecal infusions of medication, or spinal anesthesia), head trauma, and metastatic infection in patients with hospital-acquired bacteremia. Meningitis that develops after neurosurgical procedures or following penetrating cranial trauma is often caused by infection from Staphylococcus aureus, coagulase-negative staphylococci (especially Staphylococcus epidermidis), or facultative and aerobic gram-negative bacilli (including Pseudomonas aeruginosa). Most cases of meningitis associated with basilar skull fractures are caused by S. pneumoniae, H. influenzae, and group A β-hemolytic streptococci.

Aseptic meningitis refers to a disorder in which patients have clinical and laboratory evidence of meningeal irritation with negative results of routine bacterial cultures. Precise epidemiologic data on the incidence of aseptic meningitis are lacking, but aseptic meningitis is associated with an estimated 26,000 to 42,000 hospitalizations per year in the United States. The origin of aseptic meningitis is varied (Box 171.1). Enteroviruses, the leading causes of viral meningitis in adults and children, account for 50% to 75% of all cases of aseptic meningitis. Additional causes include other infections (mycobacteria, fungi, spirochetes), parameningeal infections, medications (especially nonsteroidal antiinflammatory drugs), and malignant disease. The signs and symptoms of bacterial meningitis significantly overlap with those of aseptic meningitis. This overlap led to the development of several decision rules to distinguish the two conditions. The most useful pediatric score appears to be the Bacterial Meningitis Score. This score classifies patients 1 month to 18 years old as being at very low risk of bacterial meningitis if they lack all the following criteria: positive CSF Gram stain, CSF absolute neutrophil count (ANC) of at least 1000 cells/mcL, CSF protein of at least 80 mg/dL, peripheral blood ANC of at least 10,000 cells/mcL, and a history of seizure before or at the time of presentation.11

### MEDICAL DECISION MAKING

#### ROUTINE LABORATORY TESTS

Routine testing of patients with suspected meningitis should include complete blood cell count (CBC), serum electrolytes, bicarbonate, serum urea nitrogen (BUN), creatinine, and glucose (Table 171.2). Serum lactate determinations and blood cultures are also indicated in patients with suspected meningitis.

Several newer tests have shown potential in distinguishing bacterial meningitis from nonbacterial meningitis. These tests include serum procalcitonin,12 serum C-reactive protein,13 CSF cortisol,14 and CSF lactate.15 Additional tests employing common biochemical laboratory techniques (e.g., latex agglutination, enzyme-linked immunosorbent assay, polymerase chain reaction [PCR] assay, microarrays) have shown significant promise in identifying the specific pathogen responsible for infection.

#### NEUROIMAGING BEFORE LUMBAR PUNCTURE

Selected patients with meningitis may warrant a computed tomography (CT) scan of the head, to identify patients with lesions that place them at risk for herniation from LP and to diagnose conditions that would make LP unnecessary if the patient’s work-up was limited to the LP (e.g., tumor, cerebral abscess). Unfortunately, cranial CT has inadequate sensitivity for identifying patients at risk for brain herniation. A systematic review on this subject found only a handful of cases of brain herniation that occurred following a normal cranial CT scan.16 Despite this limitation, generally accepted criteria for obtaining a cranial CT scan before LP are listed in Box 171.2. For maximal sensitivity in those patients with suspected or confirmed human immunodeficiency virus infection, contrast-enhanced cranial CT should be performed at the same time as the nonenhanced cranial CT.

**Box 171.1** Etiology of Aseptic Meningitis

**Viral Meningitis**
- Enteroviruses (e.g., coxsackievirus, echovirus, poliovirus)
- Herpes simplex viruses (HSV)
- Human immunodeficiency virus (HIV)
- West Nile virus (WNV)
- Varicella-zoster virus (VZV)
- Lymphocytic choriomeningitis virus (LCM)

**Other Pathogens**
- *Mycobacterium tuberculosis*
- *Treponema pallidum* (syphilis)
- *Borrelia burgdorferi* (Lyme disease)
- *Rickettsia rickettsiae* (Rocky Mountain spotted fever)
- Agents of ehrlichiosis
- *Cryptococcus neoformans*
- *Coccidioides immitis*

**Carcinomatous Meningitis**
- Large cell lymphomas
- Acute leukemia
- Certain solid tumors (e.g., breast cancer, lung cancer, melanoma, gastrointestinal tumors)

**Drug-Induced Meningitis**
- Nonsteroidal antiinflammatory drugs (NSAIDs)
- Trimethoprim-sulfamethoxazole
- Intravenous immune globulin

Abdominal meningitis; BUN, blood urea nitrogen; CSF, cerebrospinal fluid; Na, sodium; WBC, white blood cell count.

LUMBAR PUNCTURE AND CEREBROSPINAL FLUID ANALYSIS

Although the diagnosis of bacterial meningitis rests on CSF examination, CSF analysis alone cannot reliably distinguish bacterial and aseptic meningitis. In addition to measuring the opening pressure, the examiner should obtain four tubes of CSF, each containing 1 to 2 mL of fluid, and send them for analysis. Typically tube 1 (and/or tube 4) is sent for cell count and differential, tube 2 for protein and glucose, tube 3 for Gram stain and culture, and tube 4 for special testing or additional cultures.

In ABM, the opening pressure is usually elevated to 20 to 50 cm H₂O, although values may be lower in pediatric patients. Between 15% and 20% of adults with bacterial meningitis have a CSF opening pressure lower than 20 cm H₂O.

The appearance of the CSF can range from clear to cloudy, depending on the presence of significant concentrations of cells, bacteria, and protein. The CSF white blood cell (WBC) count can be significantly elevated, usually in the range of 1000 to 5000 cells/mm³, although this range can be quite broad (<100 to >10,000 cells/mm³). Up to 20% of adults with bacterial meningitis have a CSF WBC count lower than 100 cells/mm³, and one third of these adults have a CSF WBC count of less than 100 cells/mm³. Classically, a CSF neutrophil predominance is present (seen in 80% to 95% of cases). In 10% of cases, such as in neonatal meningitis or patients infected with L. monocytogenes, a CSF lymphocyte predominance can be seen. In resource-depleted environments, a urinary reagent strip to determine the presence of leukocyte esterase can be used as a marker for the presence of WBCs in the CSF and a point of care glucose device can be used to rapidly obtain a CSF glucose concentration.

Despite the classic teachings on CSF findings (Table 171.3), the absence of one or more typical findings is commonly seen in patients with confirmed ABM. For example, in a review of 296 episodes of ABM, 50% of patients had a CSF glucose concentration of approximately 40 mg/dL, 44% had a CSF protein level lower than 200 mg/dL, and 13% had a CSF WBC count lower than 100 cells/mm³. In another series of 696 episodes of ABM, 12% had none of the characteristic CSF findings of ABM.

Overall, the sensitivity of CSF Gram stain in bacterial meningitis ranges from 60% to 90%, depending on the concentration of the bacteria in the CSF. Sterilization of bacteria can begin to occur as soon as 15 minutes after the initiation of antibiotic therapy. A positive CSF Gram stain result is highly specific for bacterial meningitis. The following patterns are important to recognize: gram-positive diplococci suggest pneumococci; gram-negative diplococci suggest meningococci; small pleomorphic gram-negative coccobacilli suggest H. influenzae; gram-positive rods and coccobacilli suggest L. monocytogenes.

TREATMENT

Recommendations for empiric antimicrobial therapy for ABM are based on the patient’s age and predisposing conditions.

A reasonable approach to immunocompetent patients with highly suspected meningitis or meningoencephalitis consists of empiric treatment with ceftriaxone (or cefotaxime), vancomycin, and acyclovir, along with dexamethasone (Table 171.4). Acyclovir is given to cover herpes simplex virus (HSV) encephalitis, the most common cause of nonepidemid encephalitis in the United States, whose presentation can significantly overlap with that of suspected meningitis. A more conservative approach to pharmacotherapy is reasonable for stable, immunocompetent patients with normal mentation and alertness in whom CNS infection is less strongly suspected.

Treatment with high-dose dexamethasone (0.15 mg/kg intravenously, maximum dose, 10 mg, every 6 hours) before...

or concurrent with the first dose of antibiotics is thought to attenuate the inflammatory response and to lead to better outcome in children (excluding neonates) and adults with meningitis. The rationale for this approach is provided by animal studies showing that hearing loss is temporally associated with the severe inflammatory changes induced by bacterial meningitis and that dexamethasone reduces CSF synthesis of cytokines, CSF inflammation, and cerebral edema. Antibiotics should not be delayed for CT or LP when the clinical suspicion of ABM is high. Although no prospective clinical data are available on the relationship of the timing of antibiotics with clinical outcome in patients with bacterial meningitis, several retrospective reviews examined this issue and concluded that an association may exist between delayed administration of antibiotics and worse overall outcome.

Chemoprophylaxis is indicated for high-risk contacts (e.g., household, school, or work contacts) of patients with documented *N. meningitidis* or *H. influenza* type B infection, including health care providers who intubated the patient without first donning a face mask. Other health care providers do not require prophylaxis. First-line treatment is with rifampin, 10 mg/kg intravenously (to a maximum of 600 mg per dose) every 12 hours for four doses. Alternatives are ceftriaxone, ciprofloxacin, and sulfisoxazole.

### ACUTE ENCEPHALITIS

**Etiology**

Many of the viruses that cause meningitis can also cause encephalitis, but certain viruses are more likely to cause encephalitis and are responsible for most cases. These include the herpes family viruses (e.g., HSV, human herpesvirus-6 [HHV-6], varicella-zoster virus [VZV], cytomegalovirus [CMV]), arboviruses (e.g., La Crosse virus, St. Louis virus, West Nile virus [WNV], Western Equine virus, Eastern Equine virus), and enteroviruses. Although HSV is the most common cause of nonepidemic, acute focal encephalitis in the United States, the arboviruses can account for as many as 50% of cases during epidemics.

Few pyogenic bacteria cause encephalitis without overt meningitis. Syphilis, leptospirosis, brucellosis, tuberculosis, and listeriosis can be associated with encephalitis. Occasionally, encephalitis is a presenting manifestation of cryptococcosis, histoplasmosis, blastomycosis, or coccidiomycosis.

**Follow-up, Next Steps of Care, and Patient Education**

There is substantial overlap between the clinical presentation of bacterial meningitis, which is a life-threatening illness requiring rapid diagnosis, treatment, and hospital admission, and aseptic meningitis, which can often be monitored in an outpatient setting without antibiotic therapy. When a patient’s presentation is ambiguous, the emergency clinician should take into account the underlying risk factors for bacterial meningitis, the results of the physical examination, and the findings on CSF analysis. Patients with CSF profiles consistent with bacterial meningitis require hospital admission for administration of parenteral antibiotics and further monitoring. The disposition of well-appearing patients with CSF leukocytosis and findings consistent with viral meningitis is more variable. Management options include hospital admission and treatment with parenteral antibiotics or discharge with 24- to 48-hour follow-up if the patient is reliable.

The overall prognosis of ABM is poor. Mortality rates range from less than 5% for infection with *H. influenza* to 10% with *N. meningitidis* to 20% with *S. pneumoniae*.

During hospitalization, focal neurologic deficits are seen in 50% of patients, and seizures occur in 15% of patients. Cardiopulmonary failure occurs in nearly 30% of patients, and mechanical ventilation is required in almost 25% of patients. Two thirds of patients with ABM have mild or no disability using a Glasgow outcome scale. Approximately 15% of patients have moderate to severe disability following infection. The most common neurologic findings on discharge are as follows: eighth nerve cranial palsy, which occurs in nearly 15% of survivors; hemiparesis, occurring in 4% of survivors; and sixth nerve cranial palsy, occurring in 3% of survivors. Aphasia, quadriplegia, third nerve cranial palsy, and seventh nerve cranial palsy are all rare.

### Epidemiology

*Encephalitis* refers to inflammation of brain parenchyma that may coexist with inflammation of the meninges (*meningoencephalitis*) or spinal cord (*encephalomyelitis*). The overall incidence of encephalitis is reported to be 3 to 4 cases per 100,000 population. Most cases of encephalitis are often not recognized or misdiagnosed because routine care and time are sufficient for many cases to improve. Children less than 1 year of age, patients more than 65 years of age, and immunocompromised patients are at greatest risk for acute encephalitis. Viral infection is the most common identifiable cause of encephalitis, although infections with other pathogens and noninfectious causes (i.e., immune-mediated encephalitis) have been described (Table 171.5).
Access of viruses to the CNS can occur by either hematogenous or neuronal routes. For example, after an insect bite with local arboviral replication in the skin, transient viremia ensues, followed by penetration of the blood-brain barrier and the development of encephalitis. Other agents can enter through the respiratory or gastrointestinal tract or through blood transfusion or organ transplantation. Several herpes family viruses (e.g., HSV, VZV) and the rabies virus reach the CNS through retrograde travel along neuronal axons where they have gained access to nerve endings.

**PATHOPHYSIOLOGY**

Several conditions mimic the clinical presentation of acute encephalitis, notably meningitis (both bacterial and aseptic) and intracranial abscess. These conditions commonly manifest with fever, headache, altered mental status, altered level of consciousness, and focal neurologic deficits. Encephalitis should be distinguished from conditions causing encephalopathy (e.g., secondary to metabolic disturbances, hypoxia, ischemia, drugs, intoxications, organ dysfunction, or systemic infection). Encephalopathy is defined by a disruption of brain function in the absence of a direct inflammatory process in the brain parenchyma.

The physician should try to distinguish between infectious encephalitis and postinfectious or postimmunization encephalitis or encephalomyelitis. These conditions are presumed to result from an immunologic response to an antecedent antigenic stimulus provided by the infecting microorganism, immunization, or other antigens as part of the initial infection or vaccination. One example of immune-mediated encephalitis is acute disseminated encephalomyelitis (ADEM), a condition seen more commonly in children. ADEM is characterized by the abrupt onset of neurologic symptoms several days after viral illness or vaccination, generally in the absence of fever. Patients can have multifocal neurologic signs, including optic neuritis with brain and spinal cord demyelinating lesions. Disturbances in consciousness can range from stupor and confusion to coma. Treatment includes corticosteroids, plasma exchange, and intravenous immune globulin.

**PRESENTING SIGNS AND SYMPTOMS**

The syndrome of acute encephalitis shares many clinical features with acute meningitis. Patients with either syndrome may present with fever, headache, and altered level of consciousness. Although mental status changes early in the disease course are more common in patients with encephalitis, this finding does not reliably differentiate patients with encephalitis from those with bacterial meningitis. Acute encephalitis should be considered in febrile patients presenting with the following clinical features, singly or in combination: new psychiatric symptoms, cognitive defects, and diffuse or focal neurologic signs such as hemiparesis or seizure. Patients with encephalitis typically have prominent cognitive and mental changes such as lethargy, aphasia, amnestic syndrome, confusion, stupor, or even coma. In most cases, some concomitant meningeal irritation complicates the encephalitic component, and this condition is referred to as meningoencephalitis.

Clinically distinguishing among the various infectious encephalitides is difficult because of the large degree of overlap in symptoms. Epidemiologic clues that may help in directing the investigation into a cause include the following: the season of the year; the geographic locale; the prevalence of the disease in the local community; and the patient’s travel history, recreational activities, occupational exposure, insect contact, animal contact, vaccination history, and immune status. Viral affinity for certain CNS locations can provide clues to the diagnosis (Table 171.6).

**DIFFERENTIAL DIAGNOSIS**

Routine testing of patients with suspected encephalitis should include CBC, serum electrolytes, bicarbonate, BUN, creatinine, and glucose. Serum lactate determinations and blood cultures may also be indicated in patients with suspected encephalitis.

A CT scan of the brain should be performed before LP in patients suspected of having a CNS infection who also present with altered mental status, altered level of consciousness, seizures, or focal neurologic deficit. Additionally, patients with

CNS, Central nervous system; SIADH, syndrome of inappropriate anti-diuretic hormone.
a compromised immune status or with a history of CNS disease (e.g., mass lesion, stroke, focal infection) should have a CT scan prior to LP. Most patients with encephalitis have a normal CT scan; however, patients with encephalitis may show diffuse cerebral edema or, in HSV encephalitis specifically, focal edema, with or without parenchymal hemorrhages in the frontal and/or temporal lobes. Magnetic resonance imaging (MRI) is considered more sensitive and is the preferred imaging method in patients with suspected encephalitis.

Electroencephalography (EEG) is a sensitive indicator of cerebral dysfunction and may demonstrate cerebral involvement during the early stages of encephalitis. Although EEG is rarely useful in identifying a pathogen, it has a characteristic pattern of discharge in patients with HSV encephalitis (i.e., temporal focus that produces asymmetric sharp and slow waves, occurring at intervals of 2 to 3 seconds). Furthermore, EEG has a role in identifying patients with nonconvulsive seizure activity who are confused, obtunded, or comatose.

The findings on CSF analysis of patients with encephalitis may be close to normal or similar to those seen in viral infections causing aseptic meningitis (i.e., increased CSF WBC count, usually <250 cells/mm³, normal or mildly elevated CSF protein, and normal or mildly reduced CSF glucose). Red blood cells in an atraumatic LP suggest HSV encephalitis, but they can be present in other conditions (e.g., other viral encephalitides, amebic encephalitis, acute necrotizing hemorrhagic leukoencephalitis) (Box 171.3). CSF analysis is essential in patients with suspected acute encephalitis, and a CSF sample should be sent for routine analysis to exclude ABM. An additional CSF sample should be sent for nucleic acid amplification tests (e.g., PCR). A positive CSF PCR result is very helpful for documenting infection caused by a specific pathogen, but a negative PCR result cannot exclude this diagnosis. Viral cultures of CSF specimens are of limited value in patients with encephalitis and are not routinely recommended.

### TREATMENT

The treatment of acute encephalitis is mainly supportive. This includes optimization of fluid balance and electrolytes, symptomatic treatment of fever, headache, and nausea, airway protection, management of ICP, and management of seizures. Effective therapy exists for HSV and VZV infection (i.e., acyclovir, 10 mg/kg intravenously every 8 hours). Anecdotal reports of improvement have also been described with the combination of ganciclovir (5 mg/kg intravenously every 12 hours) and foscarnet (90 mg/kg intravenously every 12 hours) for CMV or HHV-6 infection and with pleconaril (5 mg/kg orally every 8 hours) for severe enteroviral disease.

</tbody>
</table>

Note: Ampicillin, 2 g IV every 4 hours, added for patients more than 50 years old and in patients with compromised immunity.

A reasonable approach to immunocompetent patients with a high suspicion of meningitis, encephalitis, or meningoencephalitis consists of empiric treatment with ceftriaxone, vancomycin, and acyclovir, along with dexamethasone (Box 171.4). These therapies should be initiated as soon as possible after blood cultures are obtained, but before CT or LP are performed. A more conservative approach to pharmacotherapy is reasonable for immunocompetent patients with normal mentation and alertness who are less likely to have CNS infection.

A key decision point in the continuation of therapy rests with the results of the Gram stain. Whereas acyclovir can be discontinued or omitted in patients with a positive Gram stain result, acyclovir should be continued or initiated in patients with a negative Gram stain result. Currently, acyclovir is given to less than one in three patients in the ED who ultimately have the diagnosis of encephalitis. Corticosteroids should be continued regardless of the results of the Gram stain. The use of corticosteroids in patients with HSV encephalitis is associated with improved outcome.

### FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT CARE

Patients with all but the mildest cases of encephalitis should be admitted to the hospital. The overall risks of death and morbidity from encephalitis are 3% to 4% and 7% to 10%, respectively. These rates are greatly influenced by the infectious pathogen and by the immune response elicited by the host. Infections with HSV, rabies virus, and Eastern Equine virus infections in immunocompromised, pediatric, and geriatric patients are all associated with a worse outcome. Before the advent of routine treatment with antiviral therapy, the mortality rate of untreated HSV encephalitis was greater than 70%, with less than 5% of the survivors returning to a normal lifestyle. The current mortality rate of HSV encephalitis in patients treated with acyclovir is less than 30%. Mortality rates of Eastern Equine, St. Louis, and La Crosse, and WNV encephalitis are greater than 30%, 20%, 10% to 15%, and 7.5%, respectively.
As with overall mortality from encephalitis, the prognosis depends on the specific etiologic agent and host factors. Significant lifelong morbidity may result from acute encephalitis. In one series that examined outcome after acyclovir-treated HSV encephalitis, 40% of surviving patients at 1 month had moderate to severe disability. Nearly 75% of the long-term survivors reported memory impairment, and approximately 50% had personality or behavioral abnormalities.22

**INTRACRANIAL ABSCESS**

**ETIOLOGY**

The bacterial pathogens responsible for the development of brain abscess depend on the age and immune status of the patient and the site of the primary infection. Streptococci (especially *Streptococcus milleri* and viridans streptococci) are the most common cause of pyogenic brain abscess resulting from extension from the nasopharynx and oropharynx. Anaerobic bacteria (e.g., *Bacteroides*, *Prevotella melaninogenica*, *Peptostreptococcus*, *Fusobacterium*, and *Actinomyces*) are additional major causes of brain abscesses, often as part of a polymicrobial infection. *S. aureus* and *Propionibacterium acnes* are seen in patients with endocarditis, in patients who have undergone neurosurgical procedures, and in patients with penetrating head trauma. Opportunistic bacterial pathogens, such as *Nocardia asteroides*, *M. tuberculosis*, and *L. monocytogenes*, as well as infection from fungal and parasitic sources, can be seen in immunocompromised patients.

**PATHOPHYSIOLOGY**

Bacteria can invade the brain by contiguous spread from nearby structures, by hematogenous penetration, or from direct implantation during surgery or penetrating head trauma. The most common contiguous infections include sinusitis, otitis media, and mastoiditis.29 Odontogenic infections (particularly involving those involving the molar teeth) account for up to 10% of cases. Hematogenous spread from distant sites of infection has been implicated in approximately 25% of brain abscesses. Endocarditis and pulmonary infections are among the most commonly reported distant foci of infection, but other sites of infection (e.g., intraabdominal, pelvic, skin, bone) can lead to the development of brain abscess. Direct implantation from invasive neurosurgical procedures or from penetrating head trauma, especially injury associated with a gunshot wound or retained foreign bone fragments, can also lead to the development of a brain abscess.29 No primary site or underlying condition can be identified in approximately one third of patients with brain abscess.

In pediatric patients, congenital heart disease is a significant risk factor for the development of a brain abscess. It accounts for 25% to 50% of the cases of brain abscesses in some pediatric series.30 Patients with cyanotic congenital heart disease have low-perfusion regions in their brain as a result of chronic severe hypoxemia and metabolic acidosis, as well as increased viscosity of the blood from secondary polycythemia, which may serve as a focus of infection. Furthermore, right-to-left shunting of the venous blood in the heart bypasses the pulmonary circulation, where phagocytes normally filter bacteria in the bloodstream.

**PRESENTING SIGNS AND SYMPTOMS**

The presenting symptoms of a brain abscess are often non-specific and vary according to several factors, including the location and size of the abscess, the underlying immune status of the host, and the virulence of the infecting organism. Common presenting signs and symptoms in brain abscess are shown in Table 171.7. Patients with intracranial abscess often have a subacute onset of illness and rarely appear toxic. Because the initial presentation is often nonspecific, the diagnosis may be initially missed in the ED, and the patient may return for subsequent visits when symptoms persist. On average, the diagnosis is made 13 to 14 days after the onset of symptoms, although symptoms can last from a few hours to several months. The most common signs and symptoms of brain abscess are headache, mental status change, focal neurologic deficit, and fever.25 The clinical triad of headache, fever, and focal neurologic deficit is present in less than 20% of cases.
The differential diagnosis in patients presenting with fever, headache, and focal neurologic deficits includes other intracranial abscesses (e.g., intracranial epidural abscess, subdural empyema), as well as meningocencephalitis. Selected patients with severe alcohol withdrawal, anticholinergic poisoning, diabetic ketoacidosis, seizures, stroke, acute psychosis, CNS tumor or mass, or other infections can present with signs and symptoms mimicking a CNS infection.

Intracranial epidural abscess is an extraaxial infection occurring in the virtual space between the dura mater and the skull. It most often occurs as a complication of neurosurgery, but it can result from spread of infection to the epidural space from the paranasal sinuses, middle ear, or mastoid process. An intracranial epidural abscess often has an insidious onset, with symptoms developing over several weeks to months. Patients present with headache, fever, and signs of increased ICP. Nuchal irritation and neurologic symptoms are unusual because the infection is typically frontal or temporal in location, and tight adherence of dura to the overlying skull limits its spread and protects the underlying brain parenchyma. The Pott puffy tumor is a rare clinical entity characterized by a frontal brain epidural abscess with overlying osteomyelitis, typically occurring as a complication of frontal sinusitis.

Subdural empyema is an infection that occurs in the potential space between the dura mater and the arachnoid, typically as a result of direct spread from paranasal sinusitis, otitis media, or mastoiditis. Unlike the epidural space, the subdural space is less restrictive, resulting in wider spread of the empyema. This spread of infection can cause inflammation of the brain parenchyma, in addition to a mass effect (and increased ICP) from the diffuse abscess. Common causative organisms are anaerobes, aerobic streptococci, staphylococci, *H. influenzae*, *S. pneumoniae*, and other gram-negative bacilli. Patients present with signs and symptoms consistent with a CNS infection, such as headache, fever, signs of increased ICP, altered level of consciousness, focal neurologic deficits, and seizures. High-resolution contrast-enhanced CT scanning is the standard technique for quick and noninvasive diagnosis of subdural empyema, although the diagnostic neuroimaging modality of choice is MRI with gadolinium enhancement.

**Differential Diagnosis**

Routine testing of patients with suspected brain abscess should include CBC, serum electrolytes, bicarbonate, BUN, creatinine, and glucose. Serum lactate determinations and blood cultures are also indicated in patients with suspected brain abscess. LP is inadvisable because of the likely presence of increased ICP and the subsequent risk of herniation.

The diagnosis of brain abscess is made by contrast-enhanced cranial CT or MRI. Nonenhanced cranial CT can identify approximately 90% of mature brain abscesses, but it is considered inadequate to exclude the diagnosis. The classic contrast-enhanced cranial CT appearance of a mature brain abscess is that of a ring-enhancing mass lesion with a hypodense center that is frequently surrounded by a substantial amount of edema. Contrast-enhanced cranial CT is highly sensitive (>95%) for identifying this type of lesion. Unfortunately, ring-enhancing lesions seen on CT images are not specific for brain abscess; cystic and necrotic neoplastic lesions, hematomas, demyelinating diseases, thrombosed giant aneurysm, and infarcted brain tissue may have the same CT characteristics. Both nonenhanced and enhanced cranial CT may miss lesions that are early in their maturity (i.e., during the “cerebritis” stage of brain abscess formation), small lesions, and lesions of the posterior circulation. Gadolinium-enhanced MRI is considered the gold standard for diagnostic imaging for this disease.

**Treatment**

Successful management of confirmed intracranial abscess involves a combination of broad-spectrum antibiotics and radiologically guided surgical drainage. Once the diagnosis is established, a neurosurgeon and an infectious disease specialist should be consulted. A sample of the infected tissue or fluid (pus) must be obtained quickly, to guide the initial therapy. The initial antibiotic regimen is based on the presumptive source of the abscess and on the Gram stain results, if available. Additional consultation with an oral-maxillofacial or ear, nose, and throat specialist may be required, depending on the extent of the primary infection. The principles of effective treatment of brain abscess are outlined in Box 171.6. Effective empiric antibiotic regimens for brain abscess are listed in Table 171.8.

Although the benefit of corticosteroids in treatment of brain abscess remains unclear, dexamethasone (10 mg intravenously loading dose, followed by 4 mg intravenously every 6 hours) is recommended when a substantial mass effect can be demonstrated on imaging. Unnecessary or prolonged use of corticosteroids should be avoided because of numerous side effects, including decreased penetration of antibiotics across the blood-brain barrier and into the abscess cavity.

**Follow-up, Next Steps in Care, and Patient Care**

Patients with brain abscess should be admitted to a monitored setting where serial neurologic examinations can take place. The sudden worsening of headache accompanied by neck

stiffness is an ominous sign in the patient with a periventricular brain abscess and may indicate rupture of the abscess into the ventricles.

Intracranial abscesses are associated with significant mortality and permanent neurologic morbidity. With the development of rapid diagnostic imaging, effective antibiotics, and improved surgical technique, reports from contemporary case series place the overall mortality from brain abscess at less than 10%. However up to 20% of the survivors will have severe neurologic disability or end up in a vegetative state. Neurologic morbidity and overall mortality are related to the initial level of consciousness at the time of diagnosis, host immune status, and response to initial therapy. Seizures occur in approximately 25% of patients with brain abscess. A frontaloparietal location of the brain abscess or underlying valvular heart disease predicts seizure development in the presence of brain abscess.

REFERENCES

Sepsis is defined as a condition in which an identified or suspected source of infection leads to a systemic inflammatory process, known as the systemic inflammatory response syndrome (SIRS) (Box 172.1). Severe sepsis refers to sepsis that has progressed to cellular dysfunction and organ damage or evidence of hypoperfusion, whereas septic shock refers to sepsis with persistent hypotension despite adequate fluid resuscitation. SIRS can develop when an exaggerated response of the body’s immune system to infection results in the release of inflammatory cytokines (tumor necrosis factor-α, interleukin-1, and interleukin-6) as the immune cells encounter the organisms’ endotoxins.6 These cytokines can lead to activation of the coagulation cascade with subsequent thrombosis and disseminated intravascular coagulation, as well as the release and activation of nitric oxide, thought to be the key mediator in vasodilation and shock.5,7 Progression of shock can lead to poor oxygen delivery and use at the tissue level, thereby creating an environment in which lactic acid is generated and mixed venous oxygenation is impaired.

**PRESENTING SIGNS AND SYMPTOMS**

The patient with classic severe sepsis or septic shock appears ill, with fever (less commonly hypothermia) and chills, an increased respiratory rate, and tachycardia. Patients may have cold skin showing outward signs of decreased perfusion (Fig. 172.1), and they may have mental status changes.

The presentation may or may not direct the clinician to the potential source of infection. For example, dyspnea and crackles on a lung examination may point to a pneumonia source, or left lower quadrant tenderness on an abdominal examination may point to diverticulitis as the source. Determining the site of infection in the emergency department (ED) may be difficult, and even retrospectively, an initial source is not determined in up to 15% of patients (Box 172.2).8 More objective measures (SIRS criteria, lactate level, mixed venous oxygenation) are used to determine whether a patient has sepsis because patients can sometimes appear surprisingly well even when they have severe sepsis or septic shock. Their only complaint may be fever, even though other SIRS criteria and hypotension may be present, especially in relatively younger, healthier, immunocompetent patients (see Fig. 172.1).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The differential diagnosis of sepsis includes many other life-threatening emergencies, including toxidromes (sympathomimetic, anticholinergic), thyrotoxicosis or myxedema coma, neuroleptic malignant syndrome, heat stroke, withdrawal (ethanol, sedative-hypnotics), pulmonary embolism, and other causes of shock (anaphylactic, cardiogenic, hypovolemic).

The diagnostic work-up may vary among patients, but most patients require standard testing to start. Serum lactate has
The presence of two or more of the following four items constitutes sepsis:

- Temperature lower than 36°C or higher than 38°C
- Heart rate greater than 90 beats per minute
- Respiratory rate greater than 20 breaths per minute or partial pressure of arterial carbon dioxide lower than 32 mm Hg
- White blood cell count lower than 4000 or higher than 12,000 cells/mm³ or more than 10% bands

The diagnostic evaluation is important, but aggressive treatment in advance of test results is essential.

**TREATMENT**

Intubation may be necessary to provide airway protection (i.e., for decreased mental status) or to decrease the work of breathing and improve oxygenation. Etomidate causes measurable, albeit transient, adrenal suppression (see Chapter 168), but the use of a single dose of etomidate as an induction agent in the ED to facilitate rapid-sequence intubation remains clinically indicated. Corticosteroids can be considered in patients with persistent hypotension unresponsive to fluids.

High-volume fluid resuscitation is required for patients with sepsis, even frail older patients, so two large-bore intravenous lines are required. Aggressive resuscitation with intravenous crystalloid (or colloid) fluids should be initiated immediately. The administration of 2 L of normal saline, or a 20 to 30 mL/kg bolus of fluids, is a good starting point.
Antibiotics should be administered early in the patient’s course. Central venous access can be established to monitor central venous pressures, to administer intravenous fluids and medications such as vasopressors, and to obtain mixed venous oxygen saturation measurements. Foley catheterization should be performed to monitor urine output. All patients should have continuous cardiac monitoring and pulse oximetry.

**SEPSIS BUNDLES**
The Institute for Healthcare Improvement developed recommendations for early, initial treatment of the patient with severe sepsis or septic shock (Box 172.3). These recommendations are based on the best current available evidence from the Surviving Sepsis Campaign’s management guidelines.15

**ANTIMICROBIAL THERAPY**
Patients should receive antibiotic coverage, early and presumptively. Coverage should be directed at the source, if known, but broad-spectrum antibiotics are generally advisable. Early administration of adequate antibiotics favors improved outcomes, whereas delays in administration result in increased mortality for this patient population.16,17

**EARLY GOAL-DIRECTED THERAPY**
Early goal-directed therapy has generated great interest and is influencing treatment for patients with severe sepsis or septic shock.3 Mortality is reduced by early identification of patients with severe sepsis (identified as patients with lactic acid >4 mmol/L) or septic shock (identified as patients with systolic blood pressure <90 mm Hg after 20 to 30 mL/kg of fluid) and by early aggressive hemodynamic monitoring and optimization using specific resuscitation end points (central venous pressure, mean arterial pressure, mixed venous oxygen saturation). Early goal-directed therapy is summarized in Figure 172.2.

**VASOPRESSORS**
In patients with persistent hypotension (mean arterial pressure < 65 mm Hg or systolic blood pressure < 90 mm Hg) despite initial fluid resuscitation (20 to 30 mL/kg), vasopressors should be used to maintain organ perfusion. First-line agents include norepinephrine, at 2 to 20 mcg/minute, or dopamine, at 5 to 20 mcg/kg/minute. Norepinephrine (Levophed) may improve survival in patients with septic shock who require vasopressor therapy, and this agent may be better at correcting hypotension while avoiding potential arrhythmias more commonly seen with dopamine.18,19 Vasopressin, at 0.01 to 0.04 units/minute, can be considered as an additional agent in patients with hypotension refractory to initial vasoactive

medications because it appears to have synergistic effects. Other second-line agents include phenylephrine and epinephrine.

**LOW-DOSE CORTICOSTEROIDS AND ACTIVATED PROTEIN C**

In addition to being less conducive to administration in the ED, low-dose corticosteroids and activated protein C have limited scope, and their use continues to be debated. In a large, multicenter trial, corticosteroids were not shown to improve survival and were also associated with an increased risk of superinfection. Shock was reversed more rapidly with corticosteroids when reversal was achieved, and previous studies showed improved survival. Corticosteroids can still be considered in patients poorly responsive to fluids and vaso-pressors. If given, corticosteroids can be administered in the form of intravenous hydrocortisone (200 to 300 mg/day as a continuous infusion or as 50-mg boluses). Adrenocorticotropic hormone stimulation testing is not necessary.

Activated protein C promotes fibrinolysis and inhibits thrombosis and inflammation. Recombinant human activated protein C, or drotrecogin alfa (activated), can be considered in high-risk patients with severe sepsis or septic shock. Identification of appropriate patients (those with an Acute Physiology and Chronic Health Evaluation II [APACHE II] score ≥25), contraindications (risk of bleeding), and cost currently limit the utility of this agent in the ED.

**FOLLOW-UP, NEXT STEPS OF CARE, AND PATIENT EDUCATION**

Patients with severe sepsis or septic shock warrant admission to an intensive care unit. An elevated lactate level is evidence of hypoperfusion. Patients without evidence of hypoperfusion, end-organ damage, or hypotension may be admitted to a medical ward. Reliance on improved vital signs alone can be misleading, and additional objective measures (serum lactate concentration, mixed venous oxygenation) are required to exclude shock states. Close monitoring of all patients is warranted because signs and symptoms can progress.

KEY POINTS

- Neutropenia is a significant risk factor for infections in patients with malignant diseases. Empiric antibiotic therapy should be administered to all neutropenic febrile patients and to afebrile neutropenic patients who have new signs and symptoms consistent with infection.
- Neutropenia is defined as an absolute neutrophil count of less than 500 cells/mm³ or an absolute neutrophil count expected to decrease to less than 500 cells/mm³ during the next 48 hours.
- Splenectomized patients are at higher risk of fulminant infection by *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Neisseria meningitidis*.
- Prolonged corticosteroid therapy (>3 to 4 weeks) at doses of more than 20 mg per day places the patient at risk of hypothalamic-pituitary-adrenal suppression and infectious complications.
- Malignant otitis externa, rhinocerebral mucormycosis, emphysematous pyelonephritis, emphysematous cholecystitis, and Fournier gangrene occur predominantly in diabetic patients.

PERSPECTIVE

Immunocompromised patients frequently visit emergency departments (EDs) for evaluation and treatment of various conditions. Infectious complications are common, and they are a diagnostic priority because clinical presentations are often subtle and atypical. This chapter covers infections in patients with malignant disease, in patients receiving immunosuppressive and corticosteroid therapy, in patients who have undergone solid organ or bone marrow transplantation, and in diabetic patients. Human immunodeficiency virus infection is discussed in Chapter 175.

MALIGNANCY, NEUTROPENIA, AND FEVER

Fever associated with neutropenia is often a presenting sign of infection in patients receiving chemotherapy for cancer.

Patients with severe neutropenia (absolute neutrophil count < 100 cells/mm³) or prolonged neutropenia (>7 days’ duration) are at higher risk of bacteremia.

PATHOPHYSIOLOGY

Patients with malignant diseases are predisposed to infections from various organisms, including bacterial, fungal, and viral pathogens. Patients with malignant disease are more prone to infections because of impairment of normal host defenses (e.g., neutropenia associated with acute leukemia), complications associated with tumor growth and spread (e.g., bronchial obstruction from bronchogenic carcinoma that results in pneumonia), the use of chemotherapeutic agents and corticosteroids, a history of splenectomy, and infections associated with intravascular catheters or other implanted devices.

Neutropenia is a significant risk factor for infections in patients with malignant disease, and it can be a result of the condition itself (e.g., acute leukemia) or a consequence of the myelosuppressive effects of agents used in disease management. The 2010 guidelines of the Infectious Disease Society of America (IDSA) for the use of antimicrobial agents in neutropenic patients with cancer defined neutropenia as an absolute neutrophil count of less than 500 cells/mm³ or an absolute neutrophil count expected to decrease to less than 500 cells/mm³ during the next 48 hours. The frequency and severity of infection are inversely proportional to the neutrophil count, and susceptibility to infection increases when the neutrophil count falls to less than 1000 cells/mm³. In addition, vulnerability to infection increases with longer periods of neutropenia. The same guidelines also defined fever, in the absence of obvious environmental causes, as a single oral temperature measurement of 38.3°C (101°F) or higher or a temperature of 38.0°C (100.4°F) or higher for at least 1 hour.

In addition to the neutrophils, other components of cell-mediated immunity, such as lymphocytes, monocytes, or macrophages, may also become deficient or defective in certain types of cancers (e.g., lymphoma, leukemia, Hodgkin disease). Many organisms may be responsible for infections in patients with these types of cancers that impair cell-mediated immunity (Box 173.1). These patients most often undergo an extensive work-up to establish the etiologic agent of infection. Special attention also needs to be paid to patients who have undergone splenectomy. These patients are at a higher risk of developing fulminant infection by *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Neisseria meningitidis*.

Approximately 60% of bacterial infections are the result of gram-positive cocci, and 35% are caused by gram-negative bacilli. Bacteremia complicates approximately 20% of the
Infections. The most common causes of bacteremia in febrile neutropenic patients are listed in BOX 173.2.14 Anaerobes are uncommon culprits in infection in neutropenic patients, except in the presence of clinical features of oral mucositis or perirectal or intraabdominal infections.2,5

Fungal infections most commonly involve Candida and Aspergillus species and are typically encountered in patients with prolonged neutropenia, or they manifest as secondary infections in patients who have received broad-spectrum antibiotics. Fungal infections can cause fever following recovery from chemotherapy-induced neutropenia. Candidal infections commonly manifest with thrush and esophagitis, and less frequently as acute disseminated candidiasis. Aspergillus infections usually manifest with sinus and pulmonary infections. This organism infects catheter sites and the gastrointestinal tract, and it causes thrombosis and infarction of blood vessels. Both Candida and Aspergillus are difficult to grow on blood cultures. Identification of these fungi requires multiple blood cultures, as well as other diagnostic tests (e.g., nasal endoscopy, biopsy of lesions).

**PRESENTING SIGNS AND SYMPTOMS**

Neutropenic patients may have fever as their only presenting feature of infection, without other specific clinical manifestations of infection. Cellulitis, pustulation, or lymphadenopathy may be diminished. A pulmonary infiltrate may be absent on initial radiographs. Meningitis and urinary tract infection may cause minimal pleocytosis and pyuria, respectively. Pain at any site should heighten the suspicion of occult infection despite the absence of typical physical signs of infection.

**MEDICAL DECISION MAKING**

The initial evaluation often includes broad diagnostic testing, including serum chemistry studies, complete blood cell count, liver and renal function tests, urinalysis, blood and urine cultures, and radiographic evaluations (e.g., plain chest radiographs). Blood cultures should be drawn before the initiation of antimicrobial therapy. When a catheter-related infection is suspected, blood cultures should be simultaneously drawn through the central venous catheter and the peripheral vein.6 Urine cultures are especially indicated if the patient has signs and symptoms of urinary tract infection, if a urinary catheter is present, or if the urinalysis results are abnormal. A chest radiograph is indicated if the patient has any respiratory abnormalities or chest discomfort. A negative chest radiograph does not rule out the presence of a pulmonary infection in a neutropenic patient. In this population of patients, multiple studies have shown that high-resolution computed tomography (CT) scanning of the chest is a better diagnostic test than plain chest radiographs for the early detection of pneumonia.7,9 Unless clinically indicated, routine lumbar puncture and cerebrospinal fluid examination are not recommended.4

**TREATMENT**

Empiric antibiotic therapy should be administered promptly to all neutropenic febrile patients and to afebrile neutropenic patients who have signs and symptoms consistent with infection. BOX 173.3 depicts recommended initial antimicrobial therapy for the management of febrile neutropenic patients.1,4,5 The 2010 IDSA guidelines1 advocated that high-risk patients should receive intravenous antimicrobial monotherapy with any one of these agents: piperacillin-tazobactam, ceftazidime, metronidazole, imipenem, or minocycline. Other antimicrobials such as vancomycin or metronidazole can be added in the presence of specific clinical situations (see BOX 173.3).

When a catheter-related infection is suspected, empiric intravenous antibiotic therapy with vancomycin should be initiated4 (see BOX 173.3). Peripheral venous catheters should be removed if the patient shows signs of infection at the site (e.g., drainage of pus, erythema) or evidence of septic shock with no other source of infection. Prompt removal of the catheter is warranted when intravascular catheterization is complicated by septic thrombophlebitis.6 The diagnosis can be made by ultrasonography with color Doppler imaging. Emergency physicians (EPs) should involve the oncologist and the infectious disease specialists in the decision-making process when considering removal of a central line.

Antiviral agents should not be initiated empirically as initial therapy in the ED for all patients with neutropenic fever. However, the presence of lesions resulting from herpes simplex virus or varicella-zoster virus warrants the initiation of antiviral agents (e.g., acyclovir, valacyclovir), even if these

pathogens are not suspected as the cause of fever. Cytomegalovirus (CMV) is an uncommon cause of fever in neutropenic patients, unless these patients undergone bone marrow transplantation. Empiric use of granulocyte or granulocyte colony-stimulating factor transfusions is not recommended for the treatment of established fever and neutropenia.

Antifungal agents (e.g., amphotericin B) should not be initiated empirically in the ED as initial therapy for all patients with neutropenic fever. When antifungal agents are considered, administration is best done in consultation with specialists. In patients with persistent fever (24 days) despite adequate antimicrobial therapy and in whom no specific cause of infection has been found, empiric antifungal therapy is often initiated by the specialists.

### ADMISSION

In general, almost all febrile neutropenic patients should be admitted to the hospital (in isolation) for intravenous antibiotic therapy and continued diagnostic work-up. Numerous studies, mostly in adult patients, have examined the identification of variables and scoring indexes that predict a low risk of severe infection among febrile neutropenic patients (Box 173.4). The most current IDSA guidelines recommended consideration of oral therapy only in low-risk adults who can be vigilantly observed and who have timely access to continued medical care. If outpatient therapy is considered, EPs should always involve the oncologist and the infectious disease specialists in the decision-making process.

### IMMUNOSUPPRESSIVE AND CORTICOSTEROID THERAPY

Chemotherapeutic agents induce variable degrees of myelosuppression. These agents can affect both the number and function of various cell lines such as neutrophils, lymphocytes, monocytes, and macrophages. The effect depends on the type of agent and the duration of exposure. Immunosuppression can be prolonged even after completion of therapy. The potential organisms and treatment of neutropenic fever associated with treatment-induced immunosuppression mirror the condition itself (see Boxes 173.1 to 173.3).

Like antitumor agents, corticosteroids can induce myelosuppression of various cell lines (e.g., lymphocytes, macrophages, immunoglobulins) and can increase the patient’s susceptibility to infections by various types of organisms. The risk of infection is directly related to the underlying condition, the dose of corticosteroid, and the duration of therapy. Prolonged treatment (≥3 to 4 weeks) at doses of more than 20 mg per day places the patient at risk for hypothalamic-pituitary-adrenal suppression and infectious complications. In addition to pyogenic bacteria, infections can also involve Mycobacterium, Aspergillus, and Listeria species. Because steroids can suppress fever, the absence of fever does not exclude the possibility of infection. Fever in patients who are receiving long-term corticosteroid therapy is infectious in origin until proven otherwise.

### SOLID ORGAN TRANSPLANTATION

The two major complications of solid organ transplantation are infections and organ rejection. These two entities have similar clinical presentations and are very difficult to differentiate with certainty based only on the initial signs and symptoms. When these complications are suspected, the patient should be isolated and admitted to the hospital. Initial evaluation in the ED includes the liberal use of blood tests (e.g., serum electrolytes, complete blood cell count, liver enzymes), urinalysis, cultures, arterial blood gas measurements (especially for patients who have undergone lung transplantation), radiographic evaluations (e.g., plain chest radiographs), and drug levels (e.g., cyclosporine). The transplant team should be notified of the patient’s clinical presentation and situation.

*Selection of the empiric regimen should be based on knowledge of the local antibiotic susceptibility pattern, prevalence of methicillin-resistant Staphylococcus aureus (MRSA) and other resistant organisms within the community, and potential drug interactions and toxicities within each patient.

†Indicated only for low-risk patients (see text and Box 173.4).

**BOX 173.4 Factors Associated with a Lower Risk of Complications and a Favorable Prognosis in Adult Patients Presenting with Neutropenic Fever**

- Absolute neutrophil and monocyte counts 100 cells/mm$^3$ or higher
- Age less than 60 and more than 16 years
- Cancer in partial or complete remission
- No symptoms or only mild to moderate symptoms of illness
- Outpatient status at the time of fever onset
- Temperature lower than 39.0°C
- Normal findings on chest radiographs
- Absence of hypotension
- Respiratory rate of up to 24 breaths per minute
- Absence of chronic pulmonary diseases and diabetes mellitus
- Absence of confusion or other signs of mental status alteration
- Absence of blood loss and dehydration
- No history of fungal infection or receipt of antifungal therapy during the 6 months before presentation with fever
The choice of antimicrobial therapy depends on the presenting clinical situation. After stabilization, the patient may require transfer to a transplant center for further evaluation. All recipients of solid organ transplants undergo similar immunosuppressive therapies after transplantation, and as a result of these standardized regimens, a predictive temporal pattern of infections (i.e., timetable of infections) is recognized. This posttransplantation timetable is a result of these standardized regimens, a predictive temporal pattern of infections (i.e., timetable of infections) is recognized (Fig. 173.1). This posttransplantation timetable is best divided into three periods: the first month, 1 to 6 months, and more than 6 months after transplantation. Opportunistic pathogens (e.g., *Pneumocystis jiroveci* [formerly *Pneumocystis carinii*], *Aspergillus fumigatus*, *Listeria monocytogenes*, *Nocardia asteroides*) are more likely to cause infections during the period from 1 to 6 months after transplantation. Prophylaxis against *Pneumocystis jiroveci* and CMV has reduced the incidence of infection by these organisms in transplant recipients.

Of all the pathogens, CMV is the single most important infectious agent affecting the recipients of solid organ transplants. The onset of infection is usually after the first month of transplantation. The clinical presentation is variable and can range from flulike illness (e.g., fever, myalgia) to pneumonitis and encephalitis. Laboratory abnormalities can include leukopenia, thrombocytopenia, mild atypical lymphocytosis, and mild hepatitis. The transplanted organ is more susceptible to infection by CMV than are native organs. CMV also has immunosuppressive properties that can render patients more susceptible to opportunistic infections. The diagnosis is made by either tissue biopsy or demonstration of viremia. For a symptomatic patient with a confirmed diagnosis, the treatment of choice is intravenous ganciclovir.

In transplant recipients, unexplained fever or headache mandates exclusion of central nervous system (CNS) infection. Evaluation should include a CT scan of the head and lumbar puncture. Because of immunosuppression, these patients may not have a high fever or signs of meningeval inflammation. Common organisms that cause CNS infections include *A. fumigatus*, *L. monocytogenes*, *Cryptococcus neoformans*, herpes viruses (e.g., CMV, Epstein-Barr virus), and *Toxoplasma gondii*.

*Aspergillus* infections, most often caused by *A. fumigatus*, are associated with a high rate of mortality in solid organ transplantation. This pathogen can be associated with various infections such as fungemia, wound infections, and sinus, pulmonary, and CNS infections. CNS infections caused by *Aspergillus* may be complicated by abscess or aneurysm formation. *Aspergillus* infection, especially in the disseminated form, is more often seen in liver transplant recipients.
BONE MARROW TRANSPLANTATION

The risk of infection in recipients of bone marrow transplants depends on various factors, such as the extent of immunosuppression before transplantation, the type of the transplant, the occurrence of graft-versus-host disease (GVHD), and the degree of immunosuppressive therapy. GVHD occurs when immunologically functioning cells in the graft attack antigens on the cells in the recipient. The clinical manifestation of GVHD is variable and involves organs such as the skin, the liver, and the gastrointestinal tract. GVHD is associated with profound immunosuppression, thus furthering the risk of infectious complications.

As in solid organ transplantation, a predictive temporal pattern of host defense defects and infectious complications occurs after bone marrow transplantation. This timetable is also best divided into three periods: the first 30 days, from 31 to 100 days, and more than 100 days after transplantation.18

The first 30 days are associated with profound leukopenia, often coupled with absolute neutropenia and lymphocytopenia. During this period, bacteremia is the most common identifiable infectious complication. The bacterial causes and the management of bacterial infections are similar to those seen in other neutropenic patients (see Boxes 173.2 and 173.3). Candida, Aspergillus, and recurrent herpes infections are also common causes of infection during this period.18

The second period, from 31 to 100 days after bone marrow transplantation, is more notable for defects in humoral and cell-mediated immunity. Leukopenia during this stage is less profound when compared with the earlier period after transplantation. Acute GVHD typically occurs during this time frame, thus prolonging the state of immunosuppression. Many organisms can cause infections in this period (see Boxes 173.1 and 173.2). The most common cause of severe viral illness during this period is CMV, which can lead to interstitial pneumonitis characterized by fever, diffuse pulmonary infiltrates, hypoxia, and the acute respiratory distress syndrome. Treatment of CMV pneumonia includes intravenous ganciclovir and CMV immunoglobulin.

The development of chronic GVHD and a delay in the development of humoral and cell-mediated immunity contribute to infectious complications during the third period (i.e., >100 days) after transplantation. Common bacterial organisms causing infections in this period include encapsulated organisms such as S. pneumoniae and H. influenzae. Candida, Aspergillus, and varicella-zoster virus are also common causes of infection during this time frame.18

DIABETES MELLITUS

Diabetes mellitus affects several aspects of the immune system. Functional properties of polymorphonuclear leukocytes, monocytes, and lymphocytes such as adherence, chemotaxis, and phagocytosis are depressed in patients with diabetes. These effects are exaggerated in patients with concomitant acidosis. Other alterations in the immune system can include reduced cell-mediated immune responses, impaired pulmonary macrophage function, and abnormal delayed-type hypersensitivity responses. No significant alternations are shown to occur with humoral immunity.19,20

Certain community-acquired infections are more common in patients with diabetes (e.g., lower respiratory tract infections, urinary tract infections, skin and mucous membrane infections). The risk of recurrence of such infections is also higher in diabetic patients. Some specific types of infections also occur predominantly in diabetic patients (e.g., malignant otitis externa, rhinocerebral mucormycosis, emphysematous pyelonephritis and cholecystitis, Fournier gangrene).19,20

Malignant Otitis Externa

Malignant otitis externa is primarily a disease of older diabetic patients. The infection involves the external auditory canal and the adjacent temporal bone. It can also involve the cranial nerves (e.g., facial nerve) and vascular structures. The primary causative organism is Pseudomonas aeruginosa. Signs and symptoms of malignant otitis externa include severe otalgia, otorrhea, edema, and cellulitis of the external auditory canal, diminished hearing, and trismus. Fever is commonly absent. Initially, the condition may be confused with nonmalignant otitis externa and perichondritis. The diagnostic work-up should include an evaluation of the extent of soft tissue involvement with radiographic studies such as contrast CT scan (preferred as the initial radiographic modality) or magnetic resonance imaging. Patients should be admitted for intravenous antimicrobial therapy (e.g., ciprofloxacin, ceftazidime, imipenem). Simultaneously, topical antipseudomonal eardrops should also be initiated. The otolaryngologist should be consulted promptly for initiating further diagnostic tests (e.g., obtaining deep tissue samples for culture and exclusion of epidermal carcinoma), as well as surgical intervention (e.g., debridement of necrotic tissue).

Mucormycosis

Mucormycosis results from infection by fungi of the order Mucorales. Most infections in humans are caused by the species Mucor and Rhizopus. The spores produced by these fungal species are ubiquitous in the environment. The disease caused by Mucoraceae almost exclusively occurs in immunocompromised individuals. A frequent predisposing condition associated with Mucorales infection is diabetes mellitus. The most common clinical manifestations are rhinocerebral and pulmonary mucormycosis.
Rhinocerebral mucormycosis involves infection of the sinuses with extension into surrounding structures (e.g., bones, orbits, brain, cavernous sinus, carotid artery, and jugular veins). Clinical manifestations depend on the extent of disease and can include fever, headache, lethargy, facial and periorbital pain and swelling, and nasal congestion (with or without discharge). On examination, the patient may have proptosis, chemosis, ulceration, and necrotic lesions on the palate or nasal mucosa, cranial nerve palsies, and hemiparesis. A vital clue to the diagnosis is the characteristic black necrotic eschars on the nasal turbinates. The definitive diagnosis is confirmed by performing biopsy and cultures of the necrotic tissue. Radiographic evaluation in the ED should include contrast CT scan or magnetic resonance imaging (preferred) of the head and neck. Management of rhinocerebral mucormycosis includes aggressive resuscitation and glycemic control, initiation of amphotericin B, and emergency surgical consultation for drainage of sinuses and debridement of infected tissues. Because the definitive diagnosis is often difficult to make in the ED, empiric broad-spectrum antimicrobial therapy for presumed bacterial infection or coinfection should be initiated.

Pulmonary mucormycosis is a rare, rapidly progressing type of pneumonia with a high mortality rate. Risk factors for acquiring the disease include diabetes, neutropenia, and other immunosuppressive conditions. Diabetic patients have impaired pulmonary macrophage function, an important mechanism in host defense against Mucoraceae. Patients may present with mild to massive hemoptysis; otherwise, pulmonary mucormycosis has no specific differentiating clinical manifestation. Chest radiography may demonstrate patchy or diffuse infiltrates, solitary nodules, or cavitary lesions. A predilection exists for involvement of the upper lobes. The definitive diagnosis requires bronchoscopy or lung biopsy. The management of pulmonary mucormycosis includes aggressive resuscitation and glycemic control, initiation of amphotericin B, and surgical consultation for potential resection of isolated pulmonary disease.

**Emphysematous Pyelonephritis**

Emphysematous pyelonephritis is a life-threatening, fulminant, suppurative, and necrotizing infection involving the renal parenchyma and perirenal tissues. The disease occurs primarily in diabetic patients and in women more frequently than in men, and it more often involves the left kidney. Patients frequently present in severe sepsis or septic shock. Emphysematous pyelonephritis can be complicated by obstruction of the renoureteral system and by the presence of renal or ureteral stones.

The diagnosis is confirmed radiographically by demonstration of gas in the renal parenchyma or perinephric space. The imaging modality of choice is noncontrast CT scan of the abdomen and pelvis. Intravenous contrast studies can be obtained for better delineation of abscess or vascular structures. Although plain film radiography may show the presence of renal calculi or gas, radiography is of limited value because of its inability to reveal detail. Renal ultrasound scanning is inferior to CT scanning for the localization of gas. Precise localization of gas is important in the differentiation of emphysematous pyelonephritis from emphysematous pyelitis (gas confined to the collecting system). Therapeutically, the distinction between the two disorders is crucial.

Emphysematous pyelonephritis usually requires nephrectomy, whereas emphysematous pyelitis often requires medical management, with a drainage procedure only if it is associated with obstruction.

Common organisms isolated from cultures of urine, blood, or aspirate material in patients with emphysematous pyelonephritis include *Escherichia coli* (most common), *Klebsiella pneumoniae*, *Proteus mirabilis*, *Enterococcus* species, and *P. aeruginosa*. Management includes intensive resuscitation, initiation of broad-spectrum antibiotics, and immediate surgical consultation and intervention. Antimicrobial therapy can include a combination of a β-lactam–β-lactamase inhibitor antibiotic with antipseudomonal activity (e.g., piperacillin-tazobactam) and an aminoglycoside (e.g., gentamicin). Surgical measures depend on the condition of the patient and the extent of disease and can include percutaneous catheter drainage, incision and drainage, or nephrectomy. Early surgical intervention (e.g., drainage, nephrectomy) in combination with broad-spectrum antibiotics has decreased mortality from emphysematous pyelonephritis.

**Emphysematous Cholecystitis**

Emphysematous cholecystitis is a rare condition primarily of older diabetic men. The clinical presentation can resemble that of typical acute cholecystitis (i.e., fever, nausea, vomiting, right upper quadrant abdominal pain). Gangrene and perforation of the gallbladder are frequent complications. Contrast CT scan of the abdomen is the imaging modality of choice for the diagnosis of emphysematous cholecystitis. The infection is often polymicrobial, with gram-negative bacilli (e.g., *E. coli*) and anaerobes (e.g., *Clostridium perfringens*). Management includes initiation of broad-spectrum antibiotics (e.g., piperacillin-tazobactam or a combination of ceftriaxone with metronidazole) and emergency cholecystectomy.

**Skin and Soft Tissue Infections**

Soft tissue infections in diabetic patients frequently involve the feet. The most common factor predisposing patients to diabetic foot infection is foot ulceration, and it is often related to peripheral neuropathy. Complications can include fulminant and life-threatening septicemia, osteomyelitis, fasciitis, and amputation.

Acute infections in patients with diabetic foot infections who have not recently received antibiotics are often polymicrobial infections with aerobic gram-positive cocci (e.g., *Staphylococcus aureus*, β-hemolytic streptococci). Chronic wounds or those that have been treated previously with antibiotics are polymicrobial infections commonly resulting from *S. aureus*, β-hemolytic streptococci, *E. coli*, *P. aeruginosa*, and *Bacteroides fragilis*. Depending on the prevalence in the community, community-associated methicillin-resistant *S. aureus* (CA-MRSA) should also be considered a culprit in these infections.

The initial assessment should include plain radiography for the exclusion of foreign bodies and for evaluation of osteomyelitis. This study also serves as a baseline for future comparisons. The ability to see or touch bone with a sterile surgical probe suggests underlying osteomyelitis. Wound specimens for aerobic and anaerobic cultures, although not usually necessary for mild infections, are best obtained by biopsy, ulcer curettage, or aspiration and are preferred to swab specimen.
Management of diabetic foot infection should include initiation of antimicrobial therapy, glycemic control, débridement of devitalized and necrotic tissue, application of sterile dressing, and off-loading pressure at the ulcer.\textsuperscript{19,24} The choice of antimicrobial therapy depends on the duration and the severity of the infection, the history of recent antibiotic therapy, the local antibiotic susceptibility pattern, and the prevalence of CA-MRSA and other resistant organisms within the community. Patients discharged home should have early follow-up to ensure proper wound healing.

Fournier gangrene, a form of necrotizing fasciitis involving the male genitalia, is typically seen in older diabetic patients. Clinical features can include crepitus, bullous skin lesions, pain out of proportion to physical findings, and marked systemic toxicity. The infection is most often polymicrobial, involving aerobic and anaerobic streptococci, \textit{S. aureus}, \textit{E. coli}, \textit{Pseudomonas}, \textit{Clostridium}, and \textit{Bacteroides} species.\textsuperscript{20} Early recognition, hemodynamic stabilization, the use of broad-spectrum antibiotics (e.g., vancomycin plus piperacillin-tazobactam plus clindamycin), and emergency surgical débridement are the mainstays of therapy. Other potential adjunctive therapeutic modalities such as hyperbaric oxygen therapy should not take precedence over early surgical intervention.

**TIPS AND TRICKS**

**Malignancy, Neutropenia, and Fever**
- Suspect occult infection when a patient complains of pain in any bodily area despite the absence of signs of infection.
- Pay special attention to the oral cavity, perineum, toes, bone marrow aspiration sites or sites, and vascular catheters for signs of infection.
- Look for a splenectomy scar. Splenectomized patients are at a higher risk of infection with \textit{Streptococcus pneumoniae}, \textit{Haemophilus influenzae}, and \textit{Neisseria meningitidis}.

**Rhinocerebral Mucormycosis**
- A vital clue to the diagnosis is the presence of characteristic black necrotic eschars on the nasal turbinates.

REFERENCES

Virulence is often mediated by the surface proteins involved in cellular attachment and entry. By producing a protein that attaches to the structural cell coat, some viruses can enhance their infectivity.

**HERPES**

The word *herpes* derives from a Greek word meaning “to creep.” This designation refers to the tendency of herpesviruses to creep along nerve pathways. Currently, at least eight identified herpesviruses cause human disease. Each has distinguishing clinical characteristics. Herpes simplex viruses (HSV-1 and HSV-2) are the agents of herpes genitalis, herpes labialis, and herpes encephalitis. VZV causes chickenpox and herpes zoster (shingles). EBV most commonly causes mononucleosis, but it has also been implicated in several lymphoproliferative syndromes. Cytomegalovirus may also manifest as mononucleosis, although it is more commonly associated with invasive disease in immunocompromised patients. Human herpesvirus 6 is the causative agent of roseola infantum. Human herpesvirus 8 has been linked to Kaposi sarcoma and Castleman disease. More recently, herpes B virus has been linked to fatal human encephalitis. Human herpesvirus 7 has been described, but it is not completely understood. As research advances, more herpes strains will likely be identified.

**HERPES SIMPLEX VIRUS**

**EPIDEMIOLOGY**

According to the U.S. Centers for Disease Control and Prevention, one out of five of the total adolescent and adult population in the United States is infected with HSV-2. The incidence is even higher for HSV-1, which infects approximately 80% of the U.S. population. HSV-1 most commonly infects the lips and leads to lesions referred to as “cold sores,” but it can also produce genital lesions. HSV-2 is most often associated with genital herpes, but this virus can infect the mouth during oral sex. The most common locations for herpes simplex lesions are the mouth and the genitals, but infections of the eyes, brain, fingers, face, and esophagus are also seen (Table 174.1).
Focal Acyclovir

The first time a patient experiences a herpes simplex outbreak (primary infection), he or she often notes a prodrome of symptoms such as fever, muscle aches, headache, malaise, and swollen lymph nodes up to a week before the skin eruptions appear. The first sign of infection of the skin appears 2 to 12 days after initial exposure and begins as cutaneous edema. The lesions typi-

HSV, Herpes simplex virus; IV, intravenously.

Presenting Signs and Symptoms
The first time a patient experiences a herpes simplex outbreak (primary infection), he or she often notes a prodrome of symptoms such as fever, muscle aches, headache, malaise, and swollen lymph nodes up to a week before the skin eruptions appear. The first sign of infection of the skin appears 2 to 12 days after initial exposure and begins as cutaneous edema. This edema is quickly followed by the development of small, grouped vesicles on an erythematous base. The lesions typically dry out and heal within 7 to 10 days, although they can last up to 3 weeks. The symptoms almost always recur and are often heralded by a prodrome of skin itching, pain, or paresthesias at the site of infection. Recurrent outbreaks often occur at the same site as the primary infection, but they tend to be milder and have a shorter duration. These recurrences can erupt in intervals of days, weeks, or years, and the triggers vary by patient.

Diagnostic Testing
Herpes simplex is typically identified clinically by the characteristic skin lesion of a thin-walled blister on an inflamed base. Definitive testing is available, and the Tzanck smear uses scrapings from lesions to identify the giant cells with inclusion bodies indicative of HSV infection. Although this test is the most readily available, it is not very sensitive. Viral cultures can be accurate if material is collected early in the illness when intact vesicles are sampled, but the sensitivity wanes with the duration of symptoms. Polymerase chain reaction testing is available and is considered the “gold standard.” It is the fastest and most accurate for testing cerebrospinal fluid (CSF). Serum immunologic studies can be used to identify specific strains of the virus, but most of these tests are time consuming and expensive. Although one point-of-care test is available for HSV-2, it is not widely used, and treatment in the emergency department is most often based on clinical suspicion.
TREATMENT AND DISPOSITION

As yet, no cure for herpes simplex exists. Some of the most exciting research is in the area of vaccination. Several vaccines in clinical trials have the potential to eliminate infection. Until then, herpes symptoms are managed using several different antiviral medications that help to reduce outbreaks and shorten the course of illness (see the “Facts and Formulas” box). The most commonly used agents are nucleosides and nucleotide analogues that block viral reproduction. They include acyclovir, valacyclovir, famciclovir, and penciclovir. Patients with a first episode of genital herpes, even with mild symptoms, should receive antiviral therapy to decrease progression to severe or prolonged symptoms. For acute outbreaks, valacyclovir and famciclovir are the most commonly prescribed medications, but they must be started within 1 day of lesion onset or during the prodrome that precedes some outbreaks. Once-daily valacyclovir can reduce the transmission rate of genital herpes by 50% to 75%. Low-dose suppressive therapy is also available for patients with frequent outbreaks. Foscarnet is a pyrophosphate analogue that can be used for treatment of HSV strains that have become resistant to the nucleosides and nucleotide analogues.

VARICELLA-ZOSTER VIRUS

EPIDEMIOLOGY

VZV is the organism that causes varicella (chickenpox) and herpes zoster (shingles). Before the initiation of the varicella vaccination program, chickenpox was a very common illness, and 90% of cases occurred in children less than 10 years of age. Although most cases were uncomplicated, chickenpox led to 11,000 hospitalizations and 100 deaths every year before the introduction of the varicella vaccine. Adolescents and adults who contracted the illness tended to have a more prolonged and severe course. Since the introduction of widespread vaccination, the incidence of chickenpox has declined by 81%, thus leading to an 88% decline in varicella-related hospitalizations.

Herpes zoster (shingles) occurs when the latent varicella virus is reactivated in the sensory ganglia. The lifetime incidence of herpes zoster is approximately 10% to 20% of the population. Although most cases are uncomplicated, herpes zoster is associated with a higher risk of complications in the elderly and immunocompromised individuals. The lifetime rate of herpes zoster in patients with acquired immunodeficiency syndrome (AIDS) is 90% to 95% of those with HIV. The incidence of herpes zoster is higher among transplant recipients and patients with other conditions that result in immunosuppression.

Facts and Formulas

\[ S_I = \frac{S_A}{B_S} \]

Antiviral Medications

Acyclovir is available in oral, injectable, and topical forms. The method of administration is determined by the site and severity of infections. It has good penetration into most tissues including cerebrospinal fluid. Compliance is difficult to achieve with acyclovir because of the need for frequent doses. Valacyclovir is an oral antiviral that is converted to acyclovir in the intestine and liver. It delivers a higher concentration of drug in the bloodstream and requires less frequent dosing. Penciclovir is converted to penciclovir within the infected cells. It has a much longer half-life than acyclovir and therefore requires less frequent dosing. Foscarnet is a pyrophosphate analogue and is used for treatment of strains of herpes simplex virus that have become resistant to the nucleosides and nucleotide analogues. It is available in an intravenous form, but it is more toxic than acyclovir. Cidofovir is used in acquired immunodeficiency syndrome and in bone marrow transplant recipients with severe infections.

PATIENT TEACHING TIPS

Herpes Simplex Symptom Relief

Keep blisters and sores clean and dry. Avoid talcum powder, synthetic materials in underwear, and tight-fitting clothing. Ice packs and over-the-counter analgesics may alleviate pain.

Urinating in the shower or bath may alleviate dysuria. Avoid sexual contact during both outbreaks and prodromes.

Preventing Transmission of Herpes Simplex

Avoid touching the sores. Wash your hands frequently. Keep personal items (e.g., towels, razors) separate during an outbreak because the virus can live for 2 hours on cloth and for 4 hours on plastic.

Viral shedding occurs without any symptoms in one third to one half of cases, and the virus can be transmitted through fluids to other people.

Use condoms (male or female) during any sexual activity, even when lesions are not present.

RED FLAGS

Varicella and Herpes Zoster

- Instruct patients about measures to prevent transmission to others.
- Admit all patients with primary varicella who are immunocompromised.
- Consult an ophthalmologist if the infection is periorbital.
- Use caution when recommending nonsteroidal antiinflammatory drugs in children with chickenpox.
- Look for evidence of complications (pulmonary, central nervous system, bacterial superinfection) in both primary and secondary varicella-zoster virus infections.
- Be sure to arrange follow-up for patients with shingles because long-term pain management may be required.
population, and most symptomatic infections occur in older or immunocompromised patients. In 2005, a safe, effective live attenuated vaccine was approved by the U.S. Food and Drug Administration and was recommended by the Advisory Committee on Immunization Practices after clinical trials demonstrated a significant reduction in morbidity secondary to herpes zoster and postherpetic neuralgia. An observational study reported a significant reduction in incidence of herpes zoster in patients 60 years old or older who received the vaccine regardless of age, race, or the presence of chronic diseases.

### PRESENTING SIGNS AND SYMPTOMS

A primary infection (chickenpox) is characterized by a diffuse, pruritic, vesicular rash 10 to 21 days after exposure. Patients with the illness typically experience a prodrome of 1 to 2 days of fever and malaise, followed by the eruption of macular lesions that progress to papules and then to vesicles that rupture and crust. Most often, the first lesions appear on the face or trunk and then spread to the extremities. Lesions may also involve the mucous membranes of the oropharynx, respiratory tract, vagina, cornea, and conjunctiva. The distinguishing feature of this rash is the presence of lesions in various stages in a single affected area. Patients less than 1 year old or more than 15 years old have the highest risk of complications, including skin infections, central nervous system involvement, and pneumonia. Chickenpox in pregnant women or neonates can lead to life-threatening pneumonitis, and primary infection during pregnancy may result in the congenital varicella syndrome.

As the patient recovers from a primary infection, the virus establishes a latent infection in the sensory dorsal root ganglia. Reactivation of this latent infection leads to the clinical symptoms of shingles. Patients frequently report a prodrome of fever, malaise, headache, and skin sensitivity before the eruption of the characteristic rash of grouped vesicles. The lesions typically crust by 7 to 10 days and resolve in 3 to 4 weeks. Pain is the most common symptom of shingles and is typically described as a burning sensation. The infection typically covers one dermatome, but it can occasionally affect neighboring dermatomes. Postherpetic neuralgia occurs in 10% to 15% of cases and is the most frequent complication of VZV. People who are more than 60 years old account for half of these cases. Postherpetic neuralgia is defined as the persistence of sensory symptoms more than 30 days after the onset of zoster. Herpes zoster ophthalmicus is a vision-threatening condition that requires opthalmologic consultation. It is caused by involvement of the ophthalmic branch of cranial nerve V. The Hutchinson sign (a lesion on the tip of the nose) suggests the diagnosis, but it is not always present. Other complications include herpes zoster oticus (Ramsay Hunt syndrome) and disseminated herpes zoster, which can be identified by the rash crossing the midline or involving several dermatomes.

### CHICKENPOX

Most cases of chickenpox follow a benign, uncomplicated course, and full recovery without chronic sequelae is expected. Treatment of varicella is aimed primarily at symptomatic relief. Acetaminophen is recommended for discomfort and fever. A small study from 1999 suggested a link between ibuprofen and necrotizing fasciitis in children with varicella. Although subsequent investigations have not been able to provide causal evidence, antinflammatory medications continue to be associated with higher risk of invasive group A streptococcal infections, and these agents are not recommended in children with chickenpox. Another prominent symptom is severe pruritus, leading to excoriation and scarring. Oral antihistamines, calamine lotion, and oatmeal baths may be helpful.

### PATIENT TEACHING TIPS

**Varicella**

Eighty percent of susceptible household contacts will contract chickenpox when they are exposed to chickenpox or shingles.

- Patients are infectious for approximately 48 hours before the onset of rash until the vesicles are crusted over (usually approximately 4 to 5 days after the appearance of the lesions).
- Illness tends to occur 10 to 21 days after exposure.
- Patients who have been vaccinated may still develop chickenpox or shingles, but the illness is generally less severe.
- People with shingles are contagious to those who have never had chickenpox or the vaccine, but you cannot “catch” shingles from someone else.
- Avoid contact with pregnant women while you are infectious.
- Do not give children with chickenpox aspirin because of its association with Reye syndrome.
- Oatmeal baths, calamine lotion, and oral antihistamines may help to alleviate pruritus.
- Consider mittens for small children to prevent excoriation and scarring.
- Acetaminophen should be given for discomfort and fever.
- A return visit to the emergency department is needed if signs of skin infection or pneumonia or changes in behavior or level of consciousness occur or if oral hydration cannot be maintained.

Several antiviral medications are active against VZV. Clinical studies have shown that these drugs may shorten the duration of illness and severity of cutaneous symptoms, but they have not been shown to reduce transmission or complications. To maximize clinical benefit, these agents should be given within 24 hours of rash onset. The decision to start antiviral therapy is based on the characteristics of the host and the extent of infection. Antiviral therapy is not recommended for cases of chickenpox in healthy children with uncomplicated infections or for use as postexposure prophylaxis. The physician should offer oral antiviral therapy to patients who are more than 13 years of age, who have chronic cutaneous or pulmonary disorders, and who are receiving long-term salicylate or steroid therapy. The most common treatment for
children is oral acyclovir, at 20 mg/kg (maximum, 800 mg/dose) four times daily for 5 days. Adults should receive 800 mg four times daily for 5 days. An obstetrician should be consulted before therapy is initiated in pregnant or peripartum women because treatment recommendations range from no treatment to admission for intravenous acyclovir. All immunocompromised patients and those who develop complications should be given intravenous acyclovir and admitted (Table 174.2).

### SHINGLES

Pharmacologic treatment of shingles is controversial. Most patients recover within 1 to 2 weeks without therapy. Up to 15% will develop postherpetic neuralgia, a potentially chronic, debilitating pain syndrome. Therapeutic trials support the use of antiviral medications to shorten the course of the acute illness and accelerate resolution of the painful neuritis, but conflict exists regarding the ability of these drugs to prevent postherpetic neuralgia. No clear difference in efficacy among the currently available antiviral medications (acyclovir, famciclovir, and valacyclovir) has been reported. Acyclovir has been studied more extensively, but the dosing regimen of five times daily limits compliance. Valacyclovir is rapidly metabolized to acyclovir, and its dosing schedule makes compliance much more likely. Steroid therapy may heal the rash more quickly, but it has not been shown to prevent postherpetic neuralgia and is not routinely recommended. Pain control is difficult in patients with acute shingles and postherpetic neuralgia. Opioids, lidocaine patches, and topical capsaicin have all been shown to provide pain relief, yet no single therapy has emerged as superior to the others. Gabapentin and amitriptyline are considered second-line agents and should be initiated in the primary care setting because patients taking these medications require close follow-up. A summary of treatment recommendations is provided in the “Priority Actions” box. Most patients with herpes zoster may be discharged to home. The exceptions include patients who are immunosuppressed or who have disseminated disease.

**Treatment of Herpes Zoster (Shingles)**

- Consider treatment with antiretroviral therapy for all eligible patients with zoster regardless of age.
- Antiretroviral therapy is strongly recommend for persons more than 50 years who have moderate or severe pain, moderate or severe rash, or involvement of nontruncal dermatomes.
- Initiate therapy as soon as possible, ideally within 72 hours of the onset of the rash.
- Prescribe valacyclovir, 1000 mg three times daily for 7 days, or famciclovir, 500 mg three times daily for 7 days (use acyclovir if cost is an issue).
- Analgesia including opioids must be provided. Consider lidocaine patches or topical capsaicin.
- Referral to primary care is needed because postherpetic neuralgia can become a chronic, debilitating disorder best managed in the outpatient setting.
Influenza viruses cause epidemic respiratory illnesses that can range from mild to severe to deadly. The virulence of influenza has tremendous year-to-year variability. In the 30-year period between 1976 and 2006, annual flu deaths ranged from a low of 3000 to a high of 49,000.\textsuperscript{12} Influenza causes disease in all age groups. During peak influenza season, the percentage of primary care office visits for influenza-like illness ranges from 3.3\% to 7.1\%.\textsuperscript{13} Each year, approximately 20\% of children and 5\% of adults develop symptomatic influenza infection.\textsuperscript{14} Although children have the highest infection rates, the rates of serious infection and death are highest in patients more than 65 years old or less than 2 years old and in patients with coexisting comorbidities.

The virus is classified as type A, B, or C, based on differences in the composition of its matrix and nucleoprotein. Human disease is caused only by influenza A and B. Influenza A is further subtyped based on the antigenicity of the hemagglutinin and neuraminidase surface glycoproteins. Currently, 16 hemagglutinin and 9 neuraminidase subtypes have been identified.\textsuperscript{15} Influenza B viruses are not further subtyped. Hemagglutinin facilitates the entry of the virus into host cells, and neuraminidase assists in the release of the progeny virions from the infected cells. These antigenic determinants are the primary basis for human immunity, thus reducing the likelihood and severity of infection in persons with prior exposure to a particular subtype. Immunity to one subtype, however, confers little to no immunity to another subtype. Antigenic variation in the surface glycoproteins causes the influenza virus to change constantly and enables it to evade immune recognition and produce repeated outbreaks of disease.

Influenza is spread through respiratory droplets that may lodge on fomites. The typical incubation period is 1 to 4 days. Adults can be infectious the day before and 5 days after symptom onset, but children can have a longer period of asymptomatic infectivity both before and after symptoms. The average number of secondary cases caused by an index case ranges from 5 to 25. In comparison, the average number of secondary cases of severe acute respiratory syndrome (SARS) caused by a single case ranges from 2.2 to 3.7.\textsuperscript{16}

Surveillance data can be used not only to determine the incidence of influenza in the community, but also to ascertain the predominant circulating type of influenza.

**Influenza Testing, Treatment, and Disposition**

Influenza testing can be performed by culture, immunofluorescence, reverse transcriptase polymerase chain reaction, or rapid tests. Because testing time is typically less than 30 minutes for the rapid diagnostic tests, these are commonly available in emergency departments. Whereas the specificity of these tests is high, the sensitivity is low. One must take care when interpreting test results because a negative result does not rule out influenza infection.\textsuperscript{17} Current guidelines encourage testing only when results will change the clinical care of the patient or influence the clinical care of other patients. Given the poor sensitivity of these tests and the recommendation that treatment not be delayed pending results, most patients do not benefit from testing.

Options for controlling influenza include immunoprophylaxis with vaccines, treatment with antiviral agents, and chemoprophylaxis. Available vaccines include inactivated influenza vaccine injection and intranasal live attenuated influenza vaccine.

Although antiviral agents are not a substitute for influenza vaccination, they can offer marginal benefit in controlling symptoms. Two classes of available agents are as follows: the adamantines (amantadine and rimantadine), which display activity against influenza A; and the neuraminidase inhibitors (zanamivir and oseltamivir), which have activity against both influenza A and B. To be effective, all these agents must be started within 48 hours of symptom onset, a feature that limits the use of these agents to patients seeking care promptly.

**Pandemic Influenza**

Influenza pandemics occur when a new virus emerges that is spread easily from person to person and to which humans have little to no immunity.\textsuperscript{18} Three major pandemics occurred in the twentieth century. Pandemic influenza differs from seasonal influenza in that young, healthy individuals are at increased risk of serious complications.

Aquatic birds likely serve as the largest reservoir for influenza viruses. Nearly all strains of influenza A circulate among wild birds, which can infect domestic fowl. Although these avian influenza viruses are not readily transmissible among humans, individuals in close contact with infected fowl may become infected. Concern exists that an avian influenza virus may mutate and trigger a pandemic. The virus that caused the catastrophic pandemic from 1918 to 1919 originated from an avian source and appears to have subsequently infected humans and adapted to allow spread among persons.\textsuperscript{19} The viruses causing the pandemics of 1957 and 1968, conversely, seem to have infected an animal (either human or pig) and reassorted with another influenza virus, resulting in the emergence of a new virus that was readily capable of human transmission.

In 2009, a novel influenza A virus (H1N1) caused a worldwide pandemic and resulted in an estimated 59 million
illnesses and 12,000 deaths in the United States.\textsuperscript{20} Although the overall case fatality rate was less than 0.5%, most serious illnesses occurred in children and young adults, with a relative sparing of adults more than 60 years old. In addition to the usual array of chronic medical conditions associated with increased morbidity, pregnancy and obesity were associated with a 4 to 15 times higher risk of hospitalization or death.

Although the overall case fatality rate for the 2009 pandemic was lower than that of seasonal influenza, several lessons were learned. Physical interventions such as hand hygiene, masks, gowns, and gloves were all found to reduce transmission.\textsuperscript{21} Similarly, resources were effectively mobilized to develop and distribute a novel vaccine that was effective at limiting disease spread. Despite effective methods to limit spread, several challenges were identified as well. Shortages of supplies during the pandemic were a significant problem. Surgical masks, N95 respirators, disinfectant wipes, and antiviral medications were all in short supply, particularly in the early stages of the pandemic.

### PATIENT TEACHING TIPS

**Suspected Influenza**

Symptoms of influenza (flu) include fever, headache, tiredness, cough, sore throat, muscle aches, and occasionally nausea, vomiting, and diarrhea.

- Rest, drink plenty of fluids, and take medications to control fever as directed by your physician.
- Flu is spread very easily from person to person through coughs and sneezes and respiratory droplets and secretions.
- Wash your hands frequently with soap and water whenever you are in contact with others.
- Cover your nose and mouth when sneezing or coughing.
- Frequently clean the surfaces of objects that may have come in contact with respiratory secretions, and use a household disinfectant labeled by the Environmental Protection Agency as having activity against bacterial and viruses.
- Monitor for symptoms of increased difficulty breathing, and seek care with a medical provider should this occur.
- If you have other medical conditions including asthma or heart disease, see a medical provider immediately if you notice worsening symptoms.
- Never give aspirin to children or teenagers with the flu without first consulting your doctor.
- Receiving the influenza vaccine in the fall can prevent flu infection.

## MONONUCLEOSIS

### EPIDEMIOLOGY

In the United States, the annual incidence of infectious mononucleosis ranges between 345 and 671 cases per 100,000.\textsuperscript{22} EBV is the principal cause, and by adulthood nearly all persons have been infected. Other viruses such as cytomegalovirus and human immunodeficiency virus can cause syndromes that resemble acute mononucleosis.

### PRESENTING SIGNS AND SYMPTOMS

In developing nations, EBV is generally a disease of the very young and is often asymptomatic or minimally symptomatic. In industrialized nations, people contract primary EBV infections at slightly later ages. In the United States, approximately one third of cases manifest during adolescence and early adulthood.\textsuperscript{23} Nearly half these patients develop clinically evident mononucleosis that can manifest classically or with typical or atypical variations of the classic presentation.

#### CLASSIC PRESENTATION

The incubation period for primary EBV infection is approximately 1 to 2 months. The disease is communicable, and saliva exchange is the most common mode of transmission. Classically, acute mononucleosis manifests in adolescence with fever, malaise, myalgias, and sore throat. The examination reveals impressive exudative tonsillitis and diffuse lymphadenopathy. The physician should palpate carefully for an enlarged spleen because splenomegaly occurs in approximately half of these patients. Symptoms usually abate within a few weeks, but prostration can occur for up to a few months.

#### TYPICAL VARIATIONS

**Hepatitis**

Intrahepatic cholestasis occurs with mononucleosis. Hepatic transaminases commonly rise to levels approximately three times normal, but jaundice is present in fewer than 10% of patients.\textsuperscript{24} Most patients recover fully.

**Rash**

A nonspecific maculopapular rash frequently develops after ampicillin or amoxicillin administration.

**Splenic Rupture**

Fifty percent of patients with acute mononucleosis develop splenic enlargement.\textsuperscript{25} The feared complication of mononucleosis is splenic rupture. Spontaneous splenic rupture occurs in 0.1% of patients with mononucleosis.\textsuperscript{25} Splenic rupture, traumatic or spontaneous, usually occurs within 3 weeks of the onset of symptoms.\textsuperscript{24}

**Fulminant Infection**

In healthy hosts, fatal or fulminant EBV infection is rare. Fatal infectious mononucleosis usually results from a rare virus-associated hemophagocytic syndrome. In these patients, the classic presentation is further coupled with fulminant hepatic dysfunction, pulmonary infiltrates, cytopenias, and rash.\textsuperscript{21}

### DIAGNOSTIC TESTING

If performed, laboratory studies may point toward mononucleosis as the cause of the patient’s viral syndrome (Table 174.3). Ultrasonography may reveal hepatosplenomegaly.
Mononucleosis
To allow the inflamed spleen to recover, restrict the patient’s athletic activity until symptoms resolve and until the spleen returns to normal size. Most authorities recommend refraining from vigorous exercise for at least 3 weeks. A longer period may be necessary in cases of persistent splenomegaly.

PATIENT TEACHING TIPS

Mononucleosis
Mononucleosis is a communicable disease. Avoid sharing saliva while you are ill.

Keep well hydrated, and control your fever with acetaminophen or ibuprofen, if the fever is bothersome.

Mononucleosis causes inflammation and enlargement of the spleen, an organ in your upper abdomen. Avoid abdominal impact.

Return if you worsen, if you have concerns, or if you develop abdominal pain.

Follow your physician’s instructions about symptom management.

Be aware of the risk of splenic rupture, and follow your physician’s instructions about returning for symptoms consistent with splenic injury.

SEVERE ACUTE RESPIRATORY SYNDROME

In February of 2003, reports of an outbreak of unexplained pneumonia that killed 5 of 305 afflicted individuals emerged in southern China.27 The disease was characterized by flulike symptoms with high fever, myalgias, nonproductive cough with dyspnea, lymphopenia, and infiltrates on chest radiography. The disease often progressed to cause respiratory failure and carried a mortality rate of 11%. The SARS epidemic serves to remind us how global travel contributes to the epidemic spread of disease. A Chinese physician who was treating patients in the afflicted region then traveled to Hong Kong, where 10 guests at his hotel were secondarily infected. These guests then traveled to Singapore, Vietnam, Canada, and the United States, thus creating the first global epidemic spread by air travel. Over the next 100 days, more than 8422 individuals were infected and 916 died in 30 countries.28 Over the next several months, SARS spread to more than 20 countries on 4 continents. The World Health Organization launched a global initiative to characterize and contain this new infection and demonstrated how concerted efforts can successfully contain epidemics. By March of 2003, the offending virus was identified as a coronavirus, termed SARS coronavirus (SARS-CoV), and the genome was mapped by April of that year. Through a remarkable globally concerted effort involving international surveillance and quarantines, SARS was effectively contained by the summer of 2003.29 The last new case was reported in April of 2004, in a scientist studying the virus in a laboratory in China (Table 174.4).

Relative to other pandemic infectious agents, the infectivity of SARS-CoV is generally low, but in some cases, a single person can infect a large number of people.33 The greatest population at risk during an epidemic seems to be health care workers because they are often in close contact with infected patients. During the 2003 epidemic, 20% of those infected were health care workers.34

WEST NILE VIRUS

EPIDEMIOLOGY

West Nile virus had not been reported in the Western Hemisphere until the first case was discovered in New York City in 1999. Since then, more than 12,000 cases of neuroinvasive disease and more than 1200 deaths have been reported in the United States. West Nile virus is a member of the Japanese encephalitis complex that includes Japanese encephalitis and St. Louis encephalitis. Birds serve as the primary reservoir for the virus. Mosquitoes become infected when they feed on afflicted birds. No known animal-to-human or human-to-human cases of transmission have occurred other than those in recipients of blood or organ transplants.

PRESENTING SIGNS AND SYMPTOMS

Approximately 80% of persons infected with West Nile virus are asymptomatic. Of those in whom symptoms develop, most will have West Nile fever, but less than 1% will have neuroinvasive disease. Characteristics of each of these illnesses are presented in Table 174.5. The incubation period for West Nile Virus infection ranges from 2 to 14 days.

DIAGNOSTIC TESTING

In most cases of infection with West Nile virus, no diagnostic testing is necessary because symptoms are usually mild and self-limited. In patients with neuroinvasive disease, testing may be necessary to differentiate the disease from other central nervous system infections requiring specific therapy. The CSF in patients with neuroinvasive disease may have lymphocyte-predominant pleocytosis. West Nile virus-specific immunoglobulin M in serum or CSF provides evidence of recent infection, but it may persist for up to 16 months. West Nile virus can also be diagnosed by using acute and convalescent serum antibody titers, as well as by nucleic acid amplification, to detect virus in CSF, serum, or tissues.

TREATMENT AND DISPOSITION

Most cases of infection with West Nile virus are asymptomatic. Almost all patients who do have symptoms have West Nile fever. Although West Nile fever is self-limited, it can last from days to months and can produce long-term sequelae. One study found that in patients hospitalized for West Nile virus infection, only 37% had total recovery at 12 months after symptom onset. Persons more than 65 years old and patients with other comorbidities have a higher incidence of long-term sequelae. Although this statement is skewed to the most serious infections, West Nile virus infection can have sequelae that outlast the acute phase of the disease.

REFERENCES

References can be found on Expert Consult @ www.expertconsult.com.
REFERENCES

In 1981, the first report of Pneumocystis (carinii) jiroveci pneumonia (PCP), in 5 healthy young men, heralded the arrival of a previously unknown pathogen and the disease it caused, later identified as human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS). Since then, the infection has spread globally and has led to the development of an array of opportunistic infections (e.g., PCP, Kaposi sarcoma, pulmonary tuberculosis) begin to appear. The immune system eventually responds to the viremia and suppresses viral replication. The viral load diminishes, and the symptoms of the acute infection resolve. Low-grade viral production continues at a steady state, and the host and virus reach a balance of viral suppression and continued viral production. This chronic steady state may be maintained for years until the immune system eventually is overwhelmed.

Infection with HIV is a progressive disease. Following years of viral replication, and eventual destruction of CD4 cells, the immune system begins to fail. During the chronic phase of infection, patients have a predictable decline of approximately 70 CD4 cells/µL/year. When the CD4 count approaches 200 cells/µL (from a normal level of approximately 1000 cells/µL), opportunistic infections (e.g., PCP, Kaposi sarcoma, pulmonary tuberculosis) begin to appear. When the CD4 cell count falls to less than 50 cells/µL, immunosuppression is profound.

**Testing**

The detection of HIV-specific antibodies in serum or plasma establishes the diagnosis of HIV infection. Tests of HIV antibodies are highly sensitive and specific. The enzyme-linked immunosorbent assay (ELISA) is the most commonly used screening test for HIV because of its high sensitivity and rapid results. All positive test results should be confirmed by
Continues at a steady rate, the new recommendations highlight the need to expand screening. Additionally, the number of persons who are newly diagnosed with HIV and who already have advanced disease is unacceptably high. Routine testing will also decrease the number of “late testers” and provide earlier entry to care. Testing now should be done on all patients 13 to 64 years old, regardless of risk factors, at all health care facilities where the prevalence of undiagnosed HIV infection is greater than 0.1%. Patients are to be informed of the testing and have the opportunity to decline or opt out of it. General consent for medical care is sufficient for testing, and special written consent for HIV testing is not required, except in the few states that continue to require written consent. Pretest and post-test counseling is no longer required.

**MONITORING INFECTION AND TREATMENT**

Monitoring the progression of infection with HIV has been likened to a runaway train on railroad tracks that lead to the edge of a cliff. The CD4 cell count is analogous to the distance between the train and the cliff, and the viral load is analogous to the speed of the train.

Close monitoring of the level of viremia and of the CD4 cell counts is crucial in the management of the HIV-infected patient. PCR testing quantitatively measures the viral RNA in copies per milliliter of plasma, the viral load. Untreated patients typically have viral loads of up to 1,000,000 copies/mL of HIV RNA. One goal of antiretroviral therapy is to decrease the viral load sufficiently to be undetectable, as occurs when fewer than 5 to 50 copies/mL of HIV RNA are present. The CD4 cell counts provide prognostic information. Patients with CD4 cell counts higher than 200 cells/µL rarely develop opportunistic infections, and those with counts higher than 50 cells/µL rarely die of HIV/AIDS.

Western blot. The Western blot test uses electrophoresis to separate HIV proteins, which produce a colored band after reacting with specific antibodies found in a sample of blood. It is the most commonly used confirmatory test and is considered the “gold standard.”

Following the initial HIV infection, antibody production occurs at such low levels that antibodies are undetected by most assays. This window period, in which HIV antibody testing leads to false-negative results, lasts approximately 4 weeks. In this setting, testing directly for the viral antigen p24 or polymerase chain reaction (PCR) testing for viral RNA may be performed. The U.S. Food and Drug Administration (FDA) has approved a newer test that detects both p24 antigen and antibodies to HIV. This highly sensitive assay, the ARCHITECHT HIV Antigen/Antibody (Ag/Ab) Combo, will be instrumental in detecting early stages of infection.

### RAPID ASSAYS

Rapid assays for detecting HIV-specific antibodies in serum can yield results in less than 30 minutes. These tests have high sensitivity and specificity and have proven effective for screening. HIV-specific antibodies may be detected in oral fluids, whole blood, serum, and plasma. Many people find oral fluid testing more acceptable than blood testing. Unfortunately, the rapid tests suffer from the same limitation as ELISA. They produce false-negative results during the window period. Positive results on rapid assays require confirmation with the Western blot.

### OPT-OUT TESTING

In 2006, the U.S. Centers for Disease Control and Prevention (CDC) revised the recommendations for HIV screening to include routine (i.e., nontargeted) testing in all health care settings, including emergency departments (EDs). Understanding that an estimated 20% of patients infected with HIV are unaware of their status and that ongoing HIV transmission continues at a steady rate, the new recommendations highlight the need to expand screening. Additionally, the number of persons who are newly diagnosed with HIV and who already have advanced disease is unacceptably high. Routine testing will also decrease the number of “late testers” and provide earlier entry to care. Testing now should be done on all patients 13 to 64 years old, regardless of risk factors, at all health care facilities where the prevalence of undiagnosed HIV infection is greater than 0.1%. Patients are to be informed of the testing and have the opportunity to decline or opt out of it. General consent for medical care is sufficient for testing, and special written consent for HIV testing is not required, except in the few states that continue to require written consent. Pretest and post-test counseling is no longer required.

**MONITORING INFECTION AND TREATMENT**

Monitoring the progression of infection with HIV has been likened to a runaway train on railroad tracks that lead to the edge of a cliff. The CD4 cell count is analogous to the distance between the train and the cliff, and the viral load is analogous to the speed of the train.

Close monitoring of the level of viremia and of the CD4 cell counts is crucial in the management of the HIV-infected patient. PCR testing quantitatively measures the viral RNA in copies per milliliter of plasma, the viral load. Untreated patients typically have viral loads of up to 1,000,000 copies/mL of HIV RNA. One goal of antiretroviral therapy is to decrease the viral load sufficiently to be undetectable, as occurs when fewer than 5 to 50 copies/mL of HIV RNA are present. The CD4 cell counts provide prognostic information. Patients with CD4 cell counts higher than 200 cells/µL rarely develop opportunistic infections, and those with counts higher than 50 cells/µL rarely die of HIV/AIDS.
Viral resistance to antiretroviral medications is an emerging phenomenon that may require alteration of a particular antiretroviral regimen. Two types of tests measure HIV resistance. The first is genotype testing, in which the sequences of the relevant viral genes are determined. The sequences reveal the presence or absence of mutations associated with antiretroviral resistance. Second, phenotypic tests excise relevant viral genes and insert them into a standard test virus. The test virus is then exposed to various antiretroviral medications to determine resistance.

**ACUTE INFECTION**

Acute HIV infection, also termed acute retroviral syndrome or primary HIV infection, is a self-limited stage that develops in the first few weeks following initial infection. During this period, viral replication is rapid and ongoing, leading to high viral loads. The CD4 cell count may decrease transiently during the acute phase. The signs and symptoms are nonspecific and most commonly include fever and rash (Box 175.1). Approximately one third of patients are asymptomatic. The average duration of illness is 14 days, but this stage may last from a few days to more than 10 weeks.3

In time, the immune system recovers. CD8 cells proliferate, and the humoral immune system produces antibodies that lead to diminishing viremia. With the falling viral load, symptoms also subside. Testing for HIV-specific antibodies (e.g., ELISA) during the early phase often produces false-negative results because of the low levels of antibodies. Testing for viral p24 antigen and PCR testing of HIV RNA are other options.

As many as one half of all new HIV transmissions are estimated to occur from persons newly infected with HIV themselves. These people are likely to have extremely high viral loads, and many are unaware of their own HIV infection and therefore continue risky behaviors. The importance of establishing the diagnosis of acute HIV infection lies in early therapy for the individual and the decrease in transmission to others.

Current guidelines recommend antiretroviral therapy (ART) for symptomatic acute HIV infection. Early treatment decreases the viral load set-point, preserves immune function, suppresses the development of viral mutations, reduces transmission, and may slow the progression to AIDS.

Acute HIV infection is often not recognized in the primary care setting because the nonspecific symptoms resemble an influenza-like illness. When patients with febrile influenza-like illnesses are evaluated, clinicians need to consider inquiring about recent (past 2 to 6 weeks) high-risk behaviors. If suspicion of acute HIV infection arises, testing should include a plasma HIV RNA assay (viral load), or p24 antigen, in addition to HIV-specific antibody testing (ELISA). Consultation with an infectious disease specialist is warranted to arrange for further testing, to assist with initial ART, and to arrange a link to future care of the patient.

**OPPORTUNISTIC INFECTIONS**

Opportunistic infections continue to be responsible for considerable morbidity and mortality in people infected with HIV. The introduction of ART has been profoundly beneficial in decreasing the number and severity of opportunistic infections. Unfortunately, not all HIV-infected people worldwide have access to ART, and resistance to ART continues to advance. The following sections discuss examples of opportunistic infections likely encountered in the ED.

**CENTRAL NERVOUS SYSTEM INFECTIONS**

**Toxoplasmosis**

The protozoan *Toxoplasma gondii* is capable of causing focal encephalitis in HIV-infected patients with severe immune suppression. This condition is rarely identified in patients with CD4 cell counts higher than 200 cells/µL, and it is most commonly found in those with CD4 cell counts lower than 50 cells/µL. Symptoms include headache, fever, and confusion. More advanced encephalitis may cause seizures and coma. Physical examination findings may include focal weakness or stupor.

The diagnosis is suggested by a contrast-enhanced computed tomography scan of the brain showing classic, multiple ring-enhancing lesions. Serologic testing for antitoxoplasmosis immunoglobulin G antibodies is helpful if the result is positive, but a negative test result cannot exclude the disease. The definitive diagnosis requires detection of the organism in a clinical sample (e.g., brain biopsy). Most patients are given empiric therapy based on a compatible clinical syndrome, typical radiographic appearance, and serologic results. Favorable response to therapy, both clinically and radiographically, supports the diagnosis. Brain biopsy is reserved for patients who fail to respond to treatment. A combination of pyrimethamine, sulfadiazine, and leucovorin (to prevent the hematologic toxicity of pyrimethamine) is the treatment of choice. Treatment is given for at least 6 weeks. Prophylactic anticonvulsants are not indicated in patients without seizures.

**PULMONARY INFECTIONS**

**Pneumocystis jiroveci**

*Pneumocystis (carinii) jiroveci* is the organism causing PCP. Despite a decline in the incidence of PCP as a result of ART and prophylaxis, many patients who are diagnosed with PCP are unaware of their underlying HIV infection. PCP is most likely to occur in patients with CD4 cell counts lower than 100 cells/µL.

Patients with PCP tend to experience a subacute illness with a dry cough, fever, and progressive dyspnea that worsens over the course of days to weeks. On physical examination, one may note tachycardia, tachypnea, and fine crackles on auscultation of the lungs. The patient may also have oropharyngeal candidiasis. Radiographs of the chest may be normal in the early stage of infection, but the common findings are bilateral and diffuse interstitial infiltrates.
The definitive diagnosis is by recovery of the organism from the lung. Expectorated sputum samples have a very low diagnostic yield and are not recommended. Bronchoalveolar lavage is the preferred method of obtaining clinical specimens. Many patients are treated empirically based on the clinical presentation, presence of hypoxia, and elevation of lactate dehydrogenase level to more than 500 mg/dL (a common but nonspecific finding in PCP). The drug of choice is trimethoprim/sulfamethoxazole, orally for mild to moderate disease and intravenously for more severe infection. Those patients with severe disease, as defined by a room air oxygen pressure of less than 70 mm Hg, should receive additional treatment with corticosteroids in the ED. The current recommendations are for a regimen of prednisone, 40 mg orally twice daily for 5 days, then 40 mg orally once daily for 5 days, then 20 mg orally once daily for an additional 11 days.

**GASTROINTESTINAL INFECTIONS**

**Mucocutaneous Candidiasis**

Candida species are frequent pathogens of the oral, pharyngeal, and esophageal mucosa. Candida albicans is the most common culprit. Infection is most often found in patients with CD4 cell counts lower than 200 cells/µL. Infection limited to the oropharynx may be mild, without symptoms, and patients may be unaware of the disease. Esophageal candidiasis more likely produces symptoms of odynophagia, burning chest discomfort, and fever.

Clinically, candidiasis appears as patches of whitish lesions on the oropharyngeal mucosa. These lesions are painless and are easily scraped off. Scrapings from these lesions may be examined microscopically with the use of potassium hydroxide to search for yeast. Scrapings may also be cultured. The diagnosis is generally made based on clinical findings. The presence of oral candidiasis, in combination with symptoms of odynophagia, suggests esophageal involvement. The definitive diagnosis of esophageal disease requires endoscopic visualization and sampling of the lesions.

Topical antifungal therapy, such as nystatin oral suspension or clotrimazole troches for 5 to 7 days, may be adequate for mild cases of oropharyngeal candidiasis. Systemic therapy with oral fluconazole is indicated for patients with recurrent disease and esophageal involvement. The safety and convenience of fluconazole (200 mg orally on the first day and then 100 mg orally once daily for a total of 7 to 14 days) make it preferable to topical therapy.

**DISSEMINATED INFECTION**

**Mycobacterium Avium Complex**

Organisms that comprise the Mycobacterium avium complex (MAC) are ubiquitous in the environment and are capable of causing disseminated and multiorgan disease in patients with profound immunosuppression. Patients at highest risk are those whose CD4 cell counts have fallen to less than 50 cells/µL. Early symptoms of disseminated MAC infection may be mild and intermittent. As the illness progresses, nonspecific symptoms of fever, diarrhea, weight loss, and fatigue develop. Some clinicians refer to these symptoms as “the dwindles.” Physical examination reveals few clues. Patients may be cachectic. Lymphadenopathy may be present, and anemia may result in pallor. The diagnosis of disseminated MAC is confirmed by isolating the organism from cultures of blood or bone marrow. Treatment of disseminated MAC infection is with a combination of antimycobacterial agents. The agents of choice are clarithromycin, ethambutol, and rifabutin.

**OPHTHALMOLOGIC INFECTIONS**

**Cytomegalovirus Retinitis**

Investigators once estimated that approximately one third of patients with AIDS would develop cytomegalovirus (CMV) retinitis, but with the introduction of potent ART regimens, new cases of CMV retinitis have greatly declined. Retinitis is the most common form of CMV disease, although gastrointestinal and neurologic manifestations of CMV infection are not unusual. CMV disease is found primarily in patients with profound immunosuppression (i.e., CD4 cell counts < 50 cells/µL). Patients with CMV retinitis may be asymptomatic, but typical symptoms include “floaters” (dark spots within the visual field that move), scotomata, or visual field defects. Symptoms primarily occur unilaterally. The diagnosis is suggested by findings on funduscopic examination, including the classic fluffy yellow-white retinal lesions. Hemorrhage into these retinal lesions leads to the appearance of “ketchup and mustard” lesions. Oral valganciclovir (900 mg orally once daily for 21 days) is the initial treatment of choice for CMV retinitis. Treatment of sight-threatening infections includes the addition of ganciclovir intraocular implants.

**IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME**

Immune reconstitution syndrome is an inflammatory condition that occurs in approximately 25% of patients following the initiation of ART for HIV infection. As immune function improves, worsening symptoms of preexisting infections, either previously treated or subclinical, develop within weeks to months after beginning ART. This paradoxical clinical deterioration in spite of immune recovery is commonly associated with mycobacterial (Mycobacterium tuberculosis and MAC) and herpesvirus infections (herpes zoster and cytomegalovirus). This syndrome tends to be self-limited, and ART is rarely interrupted. Therapy is supportive. Specific treatment of the responsible opportunistic infection may be warranted, and nonsteroidal antiinflammatory medication and steroids may be used for symptomatic relief.

**ANTIRETROVIRAL THERAPY**

The life expectancy of persons newly infected with HIV continues to increase because of advances in ART. Incredibly, most HIV-infected patients who are receiving ART will die of something other than AIDS. The goal of treatment is complete viral suppression to lower than detectable levels, to prevent viral replication and mutation that may lead to resistance. Additionally, viral suppression protects the immune system from eventual destruction. With the development of new ART, physicians increasingly design regimens that are long lasting and well tolerated, and they are more able to construct subsequent lines of therapy that can continue viral suppression. Advances in newer classes of drugs (e.g., integrase inhibitors, fusion inhibitors) offer the promise of more potency and fewer adverse effects. The development of fixed-dose combinations...
revolutionized the treatment of HIV by allowing fewer pills and less frequent dosing, thereby enhancing the tolerability of therapy. The combination pill containing efavirenz, emtricitabine, and tenofovir is dosed by one pill once a day.

Currently, 23 antiretrovirals are available (Box 175.2). The early initiation of ART can prevent the progressive destruction of the immune system that occurs even when a patient is asymptomatic and has been shown to reduce mortality markedly. Safety and tolerability of new ART regimens and increasing evidence of the detrimental effects of uncontrolled viremia led to changes in the latest management guidelines. The 2010 International AIDS Society-USA Panel revised recommendations for adults with HIV infection to include initiating ART for all asymptomatic patients with a CD4 cell count of up to 500/μL. Additionally, ART is recommended, regardless of CD4 cell count, for all symptomatic patients, as well as those who are pregnant, those with hepatitis B or C coinfection, patients with HIV-associated nephropathy, persons with active or high-risk coronary artery disease, persons more than 60 years old, patients with acute HIV infection, or persons with a high risk of HIV transmission.

Antiretroviral medications are primarily prescribed by specialists in the field and are given in various combinations to prevent the development of drug resistance. The recommendations include the combination of nucleoside and nucleotide analogue reverse transcriptase inhibitors (emtricitabine and tenofovir) with a non-nucleoside reverse-transcriptase inhibitor (efavirenz), a ritonavir-boosted protease inhibitor (atazanavir/ritonavir), or the integrase inhibitor (raltegravir). The precise combination selected depends on the patient’s individual condition. The FDA approved six fixed-dose combination pills that greatly simplified therapy and enhanced adherence.

**ADVERSE EFFECTS**

Investigators have estimated that approximately 25% of all patients will discontinue ART because of side effects. Adverse reactions may be mild to potentially life-threatening (Table 175.2). Distinguishing between these adverse effects and possible symptoms of infection with HIV or opportunistic pathogens is often difficult for clinicians. Emergency physicians must be familiar with the frequently encountered, and possibly deadly, adverse effects of ART.

Common adverse effects are primarily gastrointestinal (e.g., nausea, vomiting, diarrhea). More severe reactions include lactic acidosis. Patients often present with nonspecific symptoms such as fatigue, shortness of breath, nausea, and weight loss, and laboratory testing confirms the diagnosis by demonstrating an elevated anion gap metabolic acidosis and a serum lactate level higher than 3 mmol/L. Treatment is supportive, with immediate discontinuation of ART. Hepatotoxicity with transaminitis is primarily associated with protease inhibitors and the non-nucleoside reverse transcriptase inhibitors and warrants discontinuation of ART. Abacavir may cause a hypersensitivity reaction, usually seen within the first 6 weeks of initiating therapy, characterized by fever, myalgia, malaise, nausea, vomiting, anorexia, and rash. Symptoms progressively worsen with continued administration. Treatment is again supportive, and abacavir must be permanently discontinued. Consultation with an infectious disease expert is prudent in the management of adverse effects of ART.

**PROPHYLAXIS AGAINST COMMON OPPORTUNISTIC INFECTION**

Patients infected with HIV infection and who are severely immunosuppressed are at risk for many opportunistic infections. Long-term antimicrobial prophylaxis has been demonstrated to be beneficial in preventing several common opportunistic infections (Table 175.3).

**POSTEXPOSURE PROPHYLAXIS**

**OCCUPATIONAL EXPOSURE**

Although the risk of occupational transmission of HIV to health care workers is quite small, it is not zero. Percutaneous exposure to blood from an HIV-infected patient carries an

estimated risk of transmission of approximately 0.3%. Similar exposures to mucous membranes are associated with a 0.09% risk of transmission, and the risk of transmission following exposure to nonintact skin is even lower. The CDC provides recommendations for the management of health care workers exposed to HIV and for postexposure prophylaxis (PEP). These recommendations are based on the severity of the exposure and the viral load of the source patient (Box 175.3). Health care workers with low-risk exposures are recommended to take the basic two-drug regimens. A small-volume blood exposure to mucous membranes or nonintact skin from a source patient who is asymptomatic or who has a low viral load (<1500 RNA copies/mL) represents a low risk of infection (Box 175.4). Those with high-risk exposures are recommended to take the expanded three-drug regimen of PEP. Percutaneous exposure to a source patient with a high viral load is considered to carry a higher risk.

No PEP is recommended for any type of exposure if the source patient is HIV negative. Saliva, tears, nasal secretions,
NONOCUPATIONAL EXPOSURE

In 2005, the CDC published recommendations for antiretroviral PEP following sexual exposure, injection drug use, or other nonoccupational exposure to HIV. A 28-day course of ART is now recommended for persons seeking care less than 72 hours after nonoccunational exposure to blood, genital secretions, or other potentially infectious bodily fluid from a source known to be HIV positive.

Nonoccupational PEP (nPEP) is not always effective, and antiretroviral medications may produce harmful adverse effects, so all persons should be evaluated on a case-by-case basis. For example, persons who engage in high-risk behaviors, resulting in frequent exposures to HIV and the use of multiple and repeated courses of antiretrovirals, should not take nPEP. They should instead be counseled on risk-reduction strategies. All persons should be tested for baseline HIV infection. Additionally, they should be evaluated for other sexually transmitted diseases because the presence of these diseases may increase the risk of transmission of HIV.

Substantial exposure risk is defined as exposure of vagina, eyes, rectum, mouth, or other mucous membranes, or nonintact skin, or percutaneous contact, with blood, semen, vaginal secretions, rectal secretions, breast milk, or any bodily fluid that is visibly contaminated with blood from a source that is HIV positive. Negligible exposure risk is defined as exposure of vagina, eyes, rectum, mouth, or other mucous membranes, or nonintact skin, or percutaneous contact, with urine, nasal secretions, saliva, sweat, or tears if not visibly contaminated with blood, regardless of the known or suspected HIV status of the source. If the source’s HIV status is unknown, the source should be tested, if possible. The first dose of nPEP may be given initially, and no further doses are given if the source is determined to be HIV negative. If the source’s HIV status cannot be determined and the person seeking care had a substantial risk exposure, consideration of the source patient’s risk of having HIV is warranted. High-risk populations include men who have sex with men, commercial sex workers, those who inject drugs, those with history of incarceration, persons from countries where the HIV seroprevalence is at least 1%, or sexual partners of persons at high risk. Perpetrators of sexual assault are considered to have a high risk for HIV. Substantial exposure to high-risk populations warrants nPEP (Box 175.5).

Once the decision has been made to initiate nPEP, ART should be administered promptly. The basic regimens recommended for occupational PEP are also recommended for nPEP (see Box 175.4). The expanded regimens are reserved for patients exposed to a source population in which background resistance of HIV to ART is high.
Persons who are given nPEP must be counseled on the potential adverse effects, in particular nausea, vomiting, and diarrhea, and must be offered symptomatic therapy such as antiemetics or antimotility drugs. All persons receiving nPEP should have prompt follow-up care provided by their primary care practitioners or an infectious disease specialist.

**PREVENTION OF HIV INFECTION**

Exciting data have revealed fundamentally new, effective approaches to prevent HIV transmission. The Center for the AIDS Program of Research in South Africa (CAPRISA) study demonstrated the effectiveness and safety of a 1% vaginal gel formulation of tenofovir for the prevention of HIV acquisition in women. A double-blind, randomized controlled trial comparing tenofovir gel with placebo demonstrated a reduction in risk of HIV transmission by more than one half. This microbicidal gel allows women around the world to play a greater role in HIV prevention when compared with relying on their partners to use condoms.

The second landmark report was the Preexposure Prophylaxis Initiative (iPreEx) trial. This study, conducted in six countries, included 2499 HIV-negative men who had sex with men to evaluate whether antiretroviral medications could prevent the transmission of HIV. A once-daily antiretroviral combination pill of emtricitabine and tenofovir was compared with placebo. The participants were followed for an average of 14 months. The antiretroviral group demonstrated a 44% reduction in the incidence of HIV compared with the placebo group, and a subset of participants with enhanced compliance had an even greater risk reduction of 73%. This trial clearly showed that preexposure prophylaxis is generally safe, well tolerated, and effective. Together, these two reports demonstrate significant advances in the prevention of HIV transmission.

host defenses allow varying types of infection. Candidal infections offer a clear example of this point. Granulocytes primarily prevent bloodborne candidiasis, and this becomes apparent in neutropenic patients, who are at greater risk to develop Candida-induced fungemia and sepsis. Contrast this situation with the T-cell–mediated defense that prevents mucosal Candida proliferation. This property explains why almost 90% of patients with human immunodeficiency virus (HIV) infection have oropharyngeal colonization, and more than half develop clinical thrush. Some fungal organisms, such as Histoplasma capsulatum and Coccidioides immitis, change form during active infection of the host, and others remain exclusively in the yeast form. This adaptation allows Histoplasma and Coccidioides to infect healthy individuals.

ANATOMY
Fungal disease may occur in any organ system (central nervous system [CNS], cardiovascular system, respiratory system, skin, eyes); no system is spared. The type of infection is often associated with a specific risk factor or endemic exposure. The anatomic location of infection may be noted by the presenting symptoms. A particular area of infection may help to identify a specific deficiency in a patient’s immune system. Certain immune deficiencies are associated with specific fungal disease manifestations.

PRESENTING SIGNS AND SYMPTOMS
No specific presenting signs or symptoms are pathognomonic of fungal infection. Certain patient populations are more likely to contract fungal infections (Table 176.1).

Depending on the site of infection, presenting symptoms vary. The important signs of fungal infection are indicated by indirect evidence found in the patient’s history. Patients who have a history suggestive of greater risk for fungal infection should be evaluated and treated more extensively. For example, when a patient with acquired immunodeficiency syndrome (AIDS) presents to the emergency department (ED) after a recent admission for pneumonia with recurrent symptoms of pneumonia, the incidence of fungal infection, specifically Candida, is much higher. The patient needs cultures specifically for Candida and requires prompt antifungal therapy in the ED, in addition to broad-spectrum antibiotics covering health care–associated pneumonia.
Candidiasis, Zygomycosis, Histoplasmosis, Candidiasis

Human Activated Protein C Worldwide Evaluation in Severe Fungal sepsis is rare, but it is highly fatal. The Recombinant Sepsis puncture and prompt antifungal therapy.

Frank mental status decline. Such patients require lumbar puncture and prompt antifungal therapy.

Almost all the common fungal pathogens can cause CNS infection. The best known is Cryptococcus because of its propensity to cause meningitis in 50% to 60% of infected, immunocompromised patients. CNS infections may also be seen in much lower proportions in healthy individuals. Histoplasmosis leads to meningitis in approximately 1% of symptomatic individuals. Almost all patients with fungal meningitis present after known fungal infections and are hospitalized patients with severe immunodeficiency. This is not the case in many HIV-infected patients with cryptococcal meningitis. Patients with cryptococcal meningitis have varying presentations, often including a headache for weeks, fever, nausea, or frank mental status decline. Such patients require lumbar puncture and prompt antifungal therapy.

Sepsis (PROWESS) trial demonstrated a fungal sepsis mortality rate of nearly 56% that was more than double the nonfungal sepsis mortality rate of 28% to 30%. Suspicion is necessary to identify these patients early. A patient with a history of recent hospitalization, immunosuppression from organ transplants, or abdominal surgery has a dramatically increased risk of disseminated fungal infection causing sepsis. Cultures with specific fungal organism media should be sent, followed by initiation of antifungal therapy.

Ear, Nose, and Throat Disorders
Fungal infections in the craniofacial area may be progressive and often fatal (e.g., zygomycosis), or they may be chronic and need referral for eventual diagnosis and treatment (e.g., allergic fungal sinusitis). Zygomycosis is rare, but it is also extremely invasive and may manifest as facial pain and swelling. Patients with diabetes, especially those with diabetic ketoacidosis, require a thorough craniofacial examination to look for the characteristic black exudate. Craniofacial computed tomography (CT) scanning hastens the diagnosis when zygomycosis is suspected. Most patients with fungal sinusitis present with common sinusitis symptoms: facial pressure, congestion or drainage, swelling, and allergic “shiners.” Although most of these patients may be treated conservatively, patients with ongoing symptoms, nasal polyps, or evidence of facial deformity or bone erosion on CT will need rapid ear, nose, and throat follow-up and evaluation for débridement and antifungal therapy.

Rheumatic Disorders
Patients with disseminated fungal infections often complain of polyarthritis. Specifically, sporotrichosis spreads to the elbow or knee, and blastomycosis spreads to the weight-bearing joints or spine. Patients with cutaneous evidence of sporotrichosis or blastomycosis who have joint pain and swelling need aspiration and specific fungal analysis of the synovial fluid.

Cutaneous Disorders
The most common fungal infections in humans are the superficial cutaneous fungal infections (e.g., tinea), which are

detailed in Chapter 184. Certain fungal species may start as cutaneous lesions and disseminate to invasive disease, or they may begin as pulmonary disease and disseminate to form cutaneous lesions. The latter type is a form of blastomycosis characterized by a primary pulmonary infection that spreads, leading to cutaneous lesions in 75% of patients with disseminated disease. Sporotrichosis behaves similarly, but in an opposite fashion, because most patients with disseminated disease initially have cutaneous lesions. Both infections manifest as raised verrucous lesions with irregular borders that are painless and are often seen on the face or neck. Either infection can develop into the verrucous form or can become an extremity ulcer. Potassium hydroxide (KOH) scraping identifies these lesions as fungal.

**Vulvovaginal Disorders**

*Candida* is well known to cause a vulvovaginal infection that is common among sexually active women. This infection is often seen after a course of antibiotics, or it may appear spontaneously. Patients describe itching, burning of the labia, and a thick, white discharge. The incidence is increased in women taking oral contraceptives and in patients with diabetes. Adequate treatment is usually provided by over-the-counter antifungal creams, but patients may require oral medication if the infection is recurrent or severe.

**DIAGNOSTIC TESTING**

Fungi are usually visible in a tissue or fluid sample with the aid of KOH solution, which destroys nonfungal cell structures. This approach identifies only fungi that are easy to sample. In cases of pneumonia or fungemia, this type of testing is not usually possible. Most fungi can be cultured, and species such as *Coccidioides* and *Candida* grow readily on most agars. Other species, such as *Histoplasma* and *Aspergillus*, are much more difficult to grow and require antigen testing such as enzyme-linked immunosorbent assay to confirm infection. *Zygomycetes* requires special stains and is often a laboratory contaminant. It may be erroneously discarded if the laboratory is not told that it is a possible pathogen. Emergency physicians should call their particular hospital or outpatient microbiology laboratory to determine the best method of identification.

**SPECIFIC Fungal Infections**

**BLASTOMYCOsis**

Blastomycosis is caused by the fungus *Blastomyces dermatitidis*. This infection occurs primarily in healthy individuals who are exposed in one of the endemic areas (Table 176.2). Pulmonary infections are typical, especially in the acute phase, and are contracted though inhalation of the dormant form. After attaining body temperature, the organism transforms into the yeast form and develops a greater ability to infect. Many patients acquire the infection and have chronic pneumonia for years, often diagnosed as reactive airway disease, before the infection is discovered. Patients with chronic pulmonary infections often develop extrapulmonary manifestations of the disease. These patients frequently have cutaneous lesions, and frank meningitis occurs in 10% of disseminated cases. If CNS involvement is suspected, a simple lumbar puncture is inadequate because results are routinely negative; ventricular fluid collection is required to confirm the diagnosis.
Patients with pulmonary blastomycosis present with pneumonia: cough, fever, chills, malaise, and classic pneumonia symptoms. The chest radiographic findings can be an infiltrate or a masslike structure. This masslike appearance explains why blastomycosis is regularly diagnosed at bronchoscopy. Patients from endemic areas with symptoms resembling pneumonia and who present with mass lesions on radiography should be treated for blastomycosis, in addition to being given appropriate antibiotics. The organism can be identified by sputum smear or culture. Identification of the organism is considered to be diagnostic of infection because colonization does not occur, as it may with other fungi such as Candida. Blastomycosis does not generally clear without treatment, and untreated patients have mortality rates higher than 50%. Treating pulmonary blastomycosis is best done with the azoles, either itraconazole or ketoconazole for immunocompetent hosts. If the patient has life-threatening, disseminated disease or is immunocompromised, amphotericin B remains the most commonly recommended therapy.

**HISTOPLASMOSIS**

Histoplasmosis is caused by the fungus *H. capsulatum*. Infections regularly occur in healthy, immunocompetent individuals. The disease is prevalent in endemic areas, but it has a much greater geographic spread than blastomycosis. Histoplasma is found in caves, chicken coops, and ships hulls all over the world. Pulmonary infections are typical, and infection is often contracted through inhalation of the dormant mold form. This mold form is then activated by increased body temperatures, thus causing proliferation. Histoplasmosis has a much greater affinity for extrapulmonary symptoms than blastomycosis; spreading infection causes pericarditis, rheumatologic symptoms, and CNS involvement. Active infection depends on the load of inoculation. Lighter exposures do not produce disease, and published rates of infections higher than 50% occur in endemic areas without evidence of symptoms.

The common presentation of symptomatic histoplasmosis-induced pneumonia is indolent, with flu-like symptoms, malaise, fever, and headache in almost 100% of patients. Chest radiography is highly variable, and findings may be normal, but patchy alveolar infiltrates and hilar adenopathy are common. Disease disseminates in approximately 10% of patients, mostly immunocompromised persons, and it leads to pericarditis in 10%, arthritis and arthralgias in 10%, and meningitis in 10%. Symptoms in disseminated infection are associated with pancytopenia, with significant elevations in lactate dehydrogenase, and this condition must be differentiated from thrombotic thrombocytopenic purpura.

Identification of histoplasmosis is complicated. Culture is difficult because the organism is dangerous to laboratory personnel and must be held more than a month before results can be reported as negative. Antigen testing is helpful, but many individuals have been exposed, and complement fixation rates as high as 5% may suggest the diagnosis when it is not present. The polysaccharide antigen test is preferred, although it has problems because it cross-reacts with blastomycosis and coccidioidomycosis.

When treatment is discussed, to the physician should remember that most healthy patients without chronic or disseminated infections recover without any treatment. The current literature suggests a period of observation for otherwise healthy patients with symptomatic histoplasmosis. In making the decision to treat, the side effects of therapy must be weighed against the high likelihood of spontaneous recovery. Admittedly, this was much more of an issue before azole therapy because the side effects of treatment with amphotericin B ("amphoterrible") were sometimes worse than the infection itself.

Recommendations are to initiate treatment with oral itraconazole for a minimum of 6 weeks in patients who are hypoxic or who have not improved after 3 weeks of observation. Infected immunocompromised patients or patients with disseminated or life-threatening infections are treated best with lipid formulations of amphotericin B, with the addition of a steroid taper if pulmonary involvement is severe. Itraconazole has been used successfully in patients with HIV infection who have not developed AIDS.

**COCCIDIOIDOMYCOSIS**

Coccidioidomycosis is caused by the soil fungus *C. immitis*, which is endemic to the southwestern North American continent. Famously responsible for San Joaquin Valley fever, this organism regularly infects healthy persons. A dramatic increase in infections has been observed, with more than 100,000 infections annually in the United States alone. The increase mirrors population growth within the endemic geographic area. Infection occurs through inhalation of the mold form and subsequent transformation at body temperature into a more virulent spherule. Many infections are not symptomatic, and estimates in the literature reflect that 40% to 70% of exposed individuals never show evidence of disease. Coccidioidomycosis becomes disseminated in only 10% of cases, and much of the time only to the skin, where it frequently forms abscesses. Meningitis occurs in fewer than 5% of cases. Most complications are local, with pulmonary cavitation and chronic pneumonia responsible for the 20% of cases judged as severe.

Although primary infection usually remains in the lungs, extrapulmonary symptoms are common. Fever, chills, cough, pleuritic chest pain, and malaise are hallmarks of disease. Arthralgias and rash are also common, hence the designation “desert rheumatism.” Because only 50% of symptomatic patients have abnormal chest radiographs, the diagnosis is easy to overlook. When apparent, abnormal findings include hilar adenopathy, diffuse infiltrates, and pleural effusions. Cavitation occurs in 5% of untreated patients, and it often appears as a solitary, peripheral lesion.

Identification of *Coccidioides* is significantly easier than detection of other fungi because of the rapid growth of this organism. Most growth media produce identifiable organisms.

in 2 to 3 days. Mature spherules may also been seen in tissue biopsies with special stains, and antibody detection is helpful. Unlike in histoplasmosis, colonization is rare. Complement immunoglobulin M identification is considered a sign of active infection, and it disappears over time. Results of immunoglobulin G testing continue to remain positive in patients with chronic infection, but they also resolve when the infection clears.

Treatment of coccidioidomycosis is not always necessary because the infection often resolves without intervention. The Infectious Diseases Society of America (IDSA) reported that no evidence indicated that treating the mild form of pneumonia reduces morbidity or prevents chronic infection. Therefore, the recommendations are to treat only the following groups: immunocompromised patients, patients with severe pneumonia, and patients with suspected high inoculum loads such as after laboratory accidents. Certain ethnic groups, individuals with African or Filipino ancestry, are at greater risk of disseminated infection and should be considered more thoroughly for treatment. The precise definition of severe pneumonia is left to the physician’s judgment. Therapeutic options are similar to those in other fungal diseases, with azole therapy as first-line treatment. Some literature suggests a benefit of itraconazole over fluconazole. Both drugs are associated with a 3-month course of therapy is recommended. Disseminated disease may still be treated with the azoles if the patient is not immunocompromised. Patients with life-threatening cases require amphotericin. Patients with CNS involvement were traditionally treated with intrathecal amphotericin B. More recently, this approach was challenged by using high-dose azole therapy, and response rates were high, at 60% to 90%. However, cure was not observed, only suppression, and current thought is that a combination of intrathecal amphotericin B and intravenous azole therapy will work best.

**ASPERGILLOSIS**

The *Aspergillus* species that infects humans is most commonly *Aspergillus fumigatus*, and it is responsible for 90% of infections. *Aspergillus flavus* is less common, but it is much more likely to cause sinus disease. *Aspergillus* is a saprophyte, a soil-loving species found worldwide. Aspergillosis casts a wide spectrum of disease. It can benignly colonize immunocompetent hosts, it can cause chronic allergic symptoms, or it can devastatingly lead to overwhelming fungal sepsis in immunocompromised patients. Infection is usually contracted through inhalation of the conidia form, which progresses to the hyphae form at increased body temperature. The hyphae form is much more aggressive and difficult for the human immune system to combat. Because of the pathogenicity of the hyphae form, infection occurs in normal and immunocompromised hosts.

Immune compromised hosts who acquire aspergillosis frequently manifest disease in the form of sinusitis. The theory of the continuum of sinus disease termed allergic fungal sinusitis is controversial. *Aspergillus* has been recovered from 13% of adults with allergic fungal sinusitis. The origin is obscured by the finding that the evidence points in both directions, toward either inflammatory or infectious disease. What are not debated are the secondary effects. The accumulation of mucinous debris leads to nasal polyps and possibly more invasive disease, causing bone erosion and facial deformity.

Patients with nasal polyps should be promptly referred to an ear, nose, and throat specialist because surgical débridement is currently thought necessary for cure. Because of the complex nature of the disease, therapy should not be initiated until ear, nose, and throat consultation has been obtained, unless evidence of concomitant bacterial sinusitis is present. If clinical evidence of anatomic distortion is present, facial CT scanning is helpful in determining the extent of disease. Sinusitis is the most common form of aspergillosis in immunocompetent hosts, and pulmonary disease, particularly aspergillosis, often occurs in patients who are chronically diseased but not immunocompromised.

The long-recognized fungal ball or aspergilloma infects individuals with preexisting cavitary disease, such as tuberculosis, sarcoidosis, or bullous chronic obstructive pulmonary disease. These patients continue to have an infection rate of 10% to 15%. Symptoms, most commonly cough and hemoptysis, are difficult to discern from those of the chronic disease state in these patients. Aspergillomas are usually easily identified on plain chest radiography or on CT scans. Classic therapy involves surgical resection, and admission with surgical consultation is recommended.

Aspergillosis is the contained form of pulmonary aspergillosis. Invasive pulmonary aspergillosis is far more dangerous and must be addressed quickly. The immunocompromised patient, in particular the transplant recipient, is at great risk of contracting pulmonary aspergillosis. The incidence of *Aspergillus* in the bronchial tree of transplant recipients has been reported at 20% to 40%. Patients with AIDS have experienced an increase in invasive aspergillosis, and the current incidence has been reported at 1% to 2%. Symptoms of invasive pulmonary aspergillosis are variable, but they usually involve a combination of fever, cough, malaise, hemoptysis, and pleuritic chest pain. Heavily immunosuppressed patients present late and may have only fatigue as their first symptom, followed by massive hemoptysis or sepsis. Diagnosis in these patients is challenging, and no “gold standard” for diagnosis exists. Findings on plain radiography may be normal. Chest CT is more helpful in identifying disease, but it is not specific for aspergillosis. Serum culture for *Aspergillus* is highly specific, but it has a very low yield. Enzyme-linked immunosorbent assay may be better, although sensitivity has been reported to be as low as 60% and as high as 100%. Clinical suspicion is important, and even though no randomized study has proven the value of empiric therapy, initiating therapy before an official diagnosis has been confirmed is prudent and may be lifesaving. Even treated patients have a 20% to 100% mortality rate.

Therapy for invasive aspergillosis traditionally consisted of amphotericin B, but reported cure rates were as low as 40%. In 2002, a randomized study comparing voriconazole with amphotericin B demonstrated a significantly higher survival rate of 71% versus 58%, respectively. The study also reported an unfortunately high rate of adverse events that occurred with amphotericin B therapy in 24% of the trial participants, almost double the 13% rate in the voriconazole-treated group. The IDSA recommended voriconazole as first-line treatment for invasive disease in their most recent guidelines.

**CRYPTOCOCCOSIS**

*Cryptococcus neoformans* is an arboreal fungus found worldwide, with a predilection for the excrement of certain bird...
species, particularly pigeons. This disease was described in the 1950s to be similar to tuberculosis in terms of progression of disease in healthy individuals. Currently, Cryptococcus rarely infects immunocompetent individuals and is mainly linked to morbidity in HIV-infected individuals. Before the AIDS epidemic, infection rates were 0.8 per million in persons who were not infected with HIV. These rates spiked to 66 per 100,000 in patients with advanced HIV infection and then dropped again in that population with the advent of highly active antiretroviral therapy. Although Cryptococcus is not responsible for significant disease in otherwise healthy individuals, it is known to cause widespread asymptomatic colonization. Most adults have serum antibodies to Cryptococcus. A study of children in New York City demonstrated seroconversion before the age of 10 years.

Infection is thought to occur through inhalation of contaminated propagules (microscopic plant material), although aerosolized pigeon dander has yielded a potentially infectious yeast form of the fungus. Patients who manifest pulmonary cryptococcosis have common pneumonia symptoms: cough, fever or chills, and pleuritic chest pain. Cryptococcus has a well-known predilection for CNS involvement, and even though infection may be through inhalation, 50% to 60% of patients with cryptococcosis have CNS involvement. Patients with cryptococcal meningitis have varying presentations: often headache for weeks, fever, nausea, or frank mental status decline. Any HIV-infected patient with significant headache or mental status changes should be evaluated by lumbar puncture for cryptococcal meningitis.

The diagnosis is made with India ink examination of infected cerebrospinal fluid. Of HIV-infected patients with infected cerebrospinal fluid, 80% have organisms visible with India ink staining. Systemic involvement is often present in these patients and may be confirmed with either serum culture or latex agglutination, although latex agglutination is more accurate, with a sensitivity and specificity of more than 90%. Latex agglutination should be added to the cerebrospinal fluid studies to increase the likelihood of diagnosis.

Treatment should begin immediately in ill-appearing patients, even before lumbar puncture. The current literature points to combination therapy for CNS cryptococcosis in immunocompromised patients. Randomized trials showed that fluconazole, in combination with either amphotericin B or flucytosine, is superior to any single agent. In less severe infection such as symptomatic pneumonia in healthy individuals, oral fluconazole as monotherapy is sufficient. Revised IDSA recommendations include newer liposomal amphotericin formulations found to be effective in severe disease. Details regarding amphotericin B lipid complex (ABLC), l-amphotericin B, and amphotericin B colloidal dispersion (ABCD) are beyond the scope of this text.

CANDIDIASIS
Candida is the most common fungal pathogen seen by physicians. It is common in healthy individuals and in immunocompromised patients, and it is a frequent cause of nosocomial infection. More than 100 species of Candida have been identified. Candida albicans remains the most common species, but a rise of other species has been reported. The increase in non-albicans species is thought to be related to improved identification methods, the longer life span of immunocompromised patients, and a significant increase in the number of patients living with implantable devices.

Candida is a ubiquitous organism, existing as a yeast form and reproducing with buds and hyphae. It lives for long periods on surfaces, especially in hospital environments, but it does not commonly cause laboratory contamination. Candida can infect any organ and is sometimes seen as having a commensal relationship with healthy humans. Candida infection is fought by multiple components of the immune system. T-cell–mediated attacks prevent mucosal overcolonization, and granulocytes help to prevent candidemia. Evidence of these mechanisms is seen in the common occurrence of thrush in patients with AIDS and of Candida sepsis in neutropenic patients. The most common infection with Candida is vulvovaginal candidiasis. Although identification of vulvovaginal and oral candidiasis is almost always made clinically, identifying candidiasis in other disease states is a challenge.

Candidiasis may be diagnosed on sight, as is often the case with thrush or vulvovaginal infections. The diagnosis may be aided by a simple scraping and KOH preparation that will show the yeast or hyphae forms of the fungus. Culture is still the most common method of identification. Candida grows on most agars and is an unlikely contaminant. Unfortunately, the specificity of the culture is not matched by the sensitivity, and although the blood culture remains important, results can be misleading. In patients with autopsy-proven systemic candidiasis, the rate of recovery from blood cultures was only 40% to 60%. Because of the low sensitivity and increased incidence of invasive candidiasis, enzyme-linked immunosorbent assay and polymerase chain reaction testing are becoming more popular. Antigen testing should be pursued when invasive disease is suspected or identification of a particular species of Candida is important, such as in organ transplantation or in recent bone graft recipients. When patients develop invasive disease, treatment should be instituted when it is suspected, not when it is confirmed.

Treatment of invasive disease is much different from treatment of mucocutaneous infection. Candida can infect any organ system and has become a deadly cause of sepsis. It is now one of the top five causative organisms in sepsis. Candida sepsis has a mortality rate of 50%. Many of these cases are nosocomial, and Candida is responsible for approximately 9% of all nosocomial infections. Along with immunocompromised patients, patients with burns, patients with recent abdominal surgery, newborns, and patients receiving total parental nutrition are at risk for invasive candidiasis. Traditional treatment of disseminated candidiasis has been with amphotericin B, but intravenous fluconazole was equally effective in randomized trials in neutropenic patients. The IDSA guidelines stated that either drug may be used. Patients with recent azole exposure may have developed resistant organisms, and caspofungin should be added to the initial therapy. No convincing studies exist to prove the value of initial treatment of septic immunocompromised patients with antifungal agents, although multiple guidelines have suggested that septic patients who are at high risk for candidemia may benefit from empiric antifungal therapy. Less invasive forms of candidiasis are much more prevalent and are commonly seen in EDs.

Oral candidiasis may occur in healthy individuals after antibiotic use or in HIV-infected patients. Initial episodes should
be treated with clotrimazole troches or nystatin. If this approach is not curative or if the condition recurs, oralazole therapy should be started. Oral fluconazole and itraconazole solutions are equivalent, and both are superior to other oral therapies. HIV-infected patients with oral thrush who complain of odynophagia or retrosternal chest pain likely have esophageal involvement and should be admitted for systemic azole therapy and culture of Candida to check for resistance.

Vulvovaginal candidiasis is a common diagnosis, and 50% of women have received the diagnosis by the age of 25 years. This disorder is common after antibiotic use and is more frequent in women taking oral contraceptives. Infrequently, it can be the first sign of diabetes, and anyone who is diagnosed with vulvovaginal candidiasis for the first time should have a spot blood glucose check as a screening examination. Vulvovaginal candidiasis can be diagnosed by the combination of symptoms, visual inspection of the genitals, and KOH preparation of the scraping. Although coinfection may exist, if symptoms do not resolve, further evaluation is necessary. Patients often treat vulvovaginal candidiasis with over-the-counter agents before they see the physician. If treatment has not been attempted by patients, an over-the-counter cream should be suggested as first-line therapy. When over-the-counter treatment fails, a higher-concentration prescription azole cream is second-line therapy. An alternative is single-dose oral therapy with fluconazole or itraconazole.

**SPOROTRICHOSIS**

Sporotrichosis, or rose cutter’s disease, is caused by the fungal saprophyte Sporothrix schenckii. The fungus is found in the soil of tropical and subtropical environments, but it can be present in more austere areas, especially in greenhouses. Sporotrichosis is almost always identified as the cutaneous form in healthy individuals, although it can become disseminated through the pulmonary or cutaneous forms in immunocompromised patients. Outbreaks do occur occasionally, especially when heavy colonization is found in packed sphagnum moss that is used to protect plants (e.g., saplings, rose bushes) during transportation. More common is the sporadic case seen in plant workers, such as rose cutters.

The noninvasive form of the disease is caused by inoculation from a thorn or a skin tear during plant handling. Symptoms usually occur 3 to 4 weeks after exposure, and they begin with a small, erythematous area, usually on the forearm or hand. The lesion becomes indurated and often verrucous, and then it spreads locally to cause lymph node swelling. The lesions are not painful, but they may become superinfected with skin flora. In healthy individuals, the lesions grow very slowly and may appear the same for months. The reason for physician visits is often the cosmetic appearance. In immunocompromised patients, these skin lesions may spread. Disseminated sporotrichosis causes arthritis, often of the elbow or knee, and immunocompromised patients with suggestive skin lesions and joint effusions should be evaluated for fungal joint disease. Smaller numbers of patients with disseminated disease have pulmonary involvement. Symptoms in these patients are similar to those in patients with other types of fungal pneumonia, with presenting productive cough and pleuritic chest pain. The chest radiograph is nonspecific; interstitial infiltrates, nodules, and cavitary lesions can be seen.

Systemic illness causes constitutional symptoms such as fatigue, weight loss, and, uncommonly, fever.

The diagnosis is made with KOH examination of the cutaneous lesion scrapings. If a more specific diagnosis is required, or if extracutaneous disease is suspected, S. schenckii is easily cultured on various media, and it is identified by latex agglutination. Sporothrix is not considered a contaminant, and its presence signifies disease.

Treatment of the cutaneous form of the disease has traditionally been with saturated solution of potassium iodide (SSKI). Although theories exist, exactly how this solution works to combat sporotrichosis is unknown. The main problem with SSKI is the side effect profile. When used for more than a month, SSKI has a disabling effect on thyroid hormone production, especially in children. Itraconazole is more efficacious and has fewer side effects. Other azoles may also be used. Therapy is long, often lasting 3 to 4 months, and it should continue for a month after resolution of lesions. Patients with disseminated disease can also be treated with intravenous azoles.

**ZYGOMYCOSIS**

Zygomycosis is now the preferred term for the former mucormycosis. The preference stems from the use of zygomycosis to refer to an invasive form of disease produced by any of several Zygomycetes organisms: Absidia corymbifera, Rhizomucor pusillus, and Rhizopus arrhizus. Zygomycosis is rare, and it is almost always diagnosed in immunocompromised patients. In these patients, zygomycosis is invasive, rapidly progressive, and usually fatal. The rhinocerebral form has a mortality rate of 80% to 90%. The severity of disease is likely related to the particular affinity this group of fungi has for blood vessels. These fungi have been termed angiotrophic because of the widespread invasive blood vessel disease. This predilection for blood vessel invasion leads to ischemia, necrosis, and emboli.

Zygomycosis exists predominantly in the rhinocerebral, pulmonary, gastrointestinal, and cutaneous systems, and it may disseminate. The different forms are witnessed in particular subgroups of immunocompromised patients. The rhinocerebral form is seen in diabetic patients, especially during diabetic ketoacidosis, and in patients receiving high-dose or long-term steroids. Patients with leukemia or neutropenia often have the pulmonary form. Organ transplant recipients represent the group with the fastest-growing incidence of disease; zygomycosis represented less than 1% of fungal disease in transplant recipients in 2001, and it now represents 20%.

Symptoms of the rhinocerebral form are insidious and consist of local pain or swelling, nasal congestion, headache, fever, or epistaxis. Rhizomucor leaves a distinctive black exudate, “black pus,” that is a foreboding sign of disease. Pulmonary involvement causes cough, fever, and occasional hemoptysis, and it is usually diagnosed in extremely ill-appearing patients. Gastrointestinal involvement is also seen in significantly ill patients, and it causes hematochezia, nausea, and emesis, eventually leading to intestinal ischemia.

The diagnosis is made by tissue biopsy with microscopic examination and culture. Special stains are often needed to identify the organism accurately, and the laboratory must be
made aware that the physician is looking for *Zygomycetes*. Culture is available, but these organisms are common laboratory contaminants and are not considered diagnostic unless serial cultures are combined with direct tissue examination. Treatment should not wait for confirmation. The high mortality rate demands that treatment be initiated when the diagnosis is considered.

Rapid treatment may still not prevent death. The mortality rate of general zygomycosis is 50%, with a mortality of 80% to 90% in the rhinocerebral form. Amphotericin B is the recommended first-line therapy because the traditional azoles are not effective for zygomycosis. Members of a newer class of extended-spectrum azoles, voriconazole and posaconazole, have achieved success in patients in whom amphotericin therapy has failed.

### MEDICATION

Antifungal therapy is the primary treatment for known or suspected fungal infections. Current therapy is transitioning from amphotericin B toward more potent forms of azole medications. Amphotericin B has been used for decades for nearly every type of fungal infection and is still recommended primarily in certain situations. Because of the many situations that call for antifungal therapy, recommending one particular drug over another is impossible. A newer generation of azole medications, the triazoles, is supplanting amphotericin. These medications, including voriconazole and fluconazole, have shown superior rates of improvement and cure compared with amphotericin B. In the most serious infections such as systemic aspergillosis and zygomycosis, voriconazole and posaconazole have been directly compared with amphotericin B and have had higher cure rates and lower side effects. In less serious, but symptomatic infections, fluconazole is superior or equal to amphotericin B, with a dramatically lower side effect profile.

Helminths, Bedbugs, Scabies, and Lice Infections

Sara Lary and Kathleen J. Clem

KEY POINTS

- Immigration and travel continue to increase the parasitic diseases seen in emergency departments.
- Consider parasitic infections in patients presenting with abdominal pain, diarrhea, unexplained fever, rash, or eosinophilia.
- History of illness, travel, occupation, recreation, and behavior is paramount in diagnosing parasitic disease.

HELMINTHS

EPIDEMIOLOGY

Helmint infections are estimated to affect 1 billion people in developing countries, namely, sub-Saharan Africa, Latin America, and Asia. Most commonly seen in resource-poor areas with poor sanitation, helminthiases are increasingly recognized in refugees, immigrants, rural populations, and international travelers.

PERSPECTIVE

Parasite morbidity includes anemia, growth stunting, undernutrition, disfigurement, reduced work capacity, and increased susceptibility to other infections. Complications can include elephantiasis, blindness, gastroenterologic and urinary obstruction, and bladder cancer. Despite the widespread distribution of helminthic disease, research funding comprises less than 1% of global dollars spent.1

CLASSIFICATION

Two major phyla are responsible for human disease: Nematelminthes (roundworms) and Platyhelminthes (flatworms). Nematodes are categorized by their migration route. Enterobius and Trichuris are found intraintestinally, whereas filarial worms live in tissue and lymphatics. Platyhelminthes is further divided into two classes: cestodes, or tapeworms; and trematodes, or flukes.

Nemathelminthes (Roundworms)

Nematodes range in length from 1 mm to up to 50 cm. Intestinal nematodes include Ascaris, Necator, and Ancylostoma, which develop in soil, whereas Strongyloides and Enterobius can be directly transmitted from person to person. With the exception of Strongyloides, most helminthes do not undergo replication within the host. Nematodes causing human disease include Dracunculus and filarial worms such as Wucheria, Brugia, and Onchocerca.

INTESTINAL ROUNDWORMS: ASCARIS

EPIDEMIOLOGY

Ascariasis infects approximately 25% of the world’s population.12 It is prevalent in warm countries and areas of poor sanitation and is endemic to the southern United States. Ova can remain infective for several years. They are sensitive to temperatures higher than 65° C or lower than 20° C, direct sunlight, and organic solvents. Ascaris lumbricoides reaches up to 40 cm and is characterized by a constricted area at the junction of the first and middle thirds. The golden brown ovoid eggs measure 60 by 40 mcm.

TRANSMISSION AND LIFE CYCLE

Ascariasis is transmitted by ingesting mature eggs from contaminated soil or in conjunction with human feces used as fertilizer. Infection may cross into nonendemic areas through vegetable transport and tainted water. Children frequently contract the disease by playing in dirt. Fertilized eggs become infective in soil 3 to 4 weeks after excretion. When the eggs are swallowed, the larvae hatch in the duodenum, penetrate the intestinal wall, and migrate through the portal venous system to the liver. The larvae migrate through the right side of the heart, the lungs, and into the tracheobronchial tree. Over 2 weeks, the larvae are
carried up the trachea to the larynx, where they move into the esophagus and are swallowed a second time, to reach the small intestine, where they mature. Female *Ascaris* worms lay eggs 2 to 3 months after ingestion and produce up to 240,000 eggs per day. The life span of *Ascaris* is 6 months to 1 year. *Ascaris* coexists with *Trichuris trichiura* in the United States, predominantly in the Appalachian Mountains.

**PRESENTING SIGNS AND SYMPTOMS**

Many patients are asymptomatic or have mild symptoms, and the infection ends after expulsion of the adult worms. Ectopic migration is possible, and it causes severe clinical manifestations. The pulmonary larval migration occurs 9 to 12 days after egg ingestion and may manifest with cough, bloody or mucoid sputum, pleurisy, and fever.

Eosinophilia develops during this pulmonary migration and may manifest as eosinophilic pneumonitis, known as Loeffler syndrome. Chest radiographs may demonstrate small, rounded infiltrates that are transient and usually resolve after several weeks. Loeffler syndrome is seen mainly in ascariasis, but it also may occur in other parasitic infections such as hookworm infestation and strongyloidiasis. Allergic reaction can occur with reinfection. Two to 3 months after ingestion, the parasite matures in the small intestine and can cause abdominal pain, nausea, vomiting, anorexia, diarrhea, constipation, volvulus, or intussusception. Biliary obstruction and intestinal inflammation can manifest as an acute surgical abdomen, mimicking acute appendicitis or cholecystitis. Liver abscesses and pancreatitis are possible when the female worm migrates up the common bile duct. Protein malnutrition and intestinal obstruction are more likely to occur in heavily infected children rather than in adults.

**DIAGNOSIS AND MEDICAL DECISION MAKING**

The diagnosis can be made from the passage of worms in the stool or by finding eggs in the feces. A single stool specimen sent for ova and parasite examination is usually sufficient. As the worm transverses the esophagus, it may be coughed out. In eosinophilic pneumonitis, larvae may be isolated from sputum or gastric aspirate.

Gastrointestinal radiographic examination may visualize adult worms on contrast studies, ultrasound scans of the pancreatic-biliary system, plain abdominal films, and endoscopic retrograde cholangiopancreatography (ERCP). ERCP can be therapeutic in extracting worms. Serologic antibody tests include complement fixation, precipitin, agar gel diffusion, immunoendorphoresis, and the radioallergosorbent test.

**INTESTINAL ROUNDWORMS: NECATOR AND ANCYLOSTOMA (HOOKWORMS)**

**EPIDEMIOLOGY**

Hookworm infestations of *Ancylostoma duodenale* prevail in southern Europe, northern Asia, and North Africa, whereas *Necator americanus* is the main species affecting the Western Hemisphere and equatorial Africa. Worldwide, 1 billion persons are believed to be infected with hookworms. The frequency of infection is a general indication of the local level of hygiene and sanitation. Disease burden from hookworms results in iron-deficiency anemia and hypoproteinemia.

**PRESENTING SIGNS AND SYMPTOMS**

Hookworm infection is contracted by penetration of the skin or oral mucosa by filariform larvae. Persons who walk barefoot on contaminated soil or who eat contaminated vegetables become infected. Transplacental infection and transmammary infection are also possible. Eggs are passed in the stools to the soil, where they hatch into rhabditiform larvae that develop into filariform larvae. The larvae penetrate the skin or mucosa directly and reach the alveoli through the circulation. The larvae then ascend the airway, enter the esophagus, are swallowed, and reach the small intestine, where they mature.

Adult worms use hooks to attach to the intestinal mucosa, and they suck blood directly from the host. The time frame from skin invasion to egg appearance is 6 to 8 weeks. *Ancylostoma* adults live on average for 6 to 8 years, and the life span of *Necator* ranges from 2 to 5 years, but both species of worms can survive for more than a decade.

**DIAGNOSIS AND MEDICAL DECISION MAKING**

Presentation includes rash, cough, low-grade fever, abdominal pain, diarrhea, generalized weakness, weight loss, heme-positive stools, and eosinophilia. Early larval invasion of the skin causes pruritus and erythematous maculopapular or vesicular dermatitis, known as “ground itch.” Sensitized hosts may have serpiginous tracts as larvae migrate through the subcutaneous tissue, similar to cutaneous larva migrans.

Transient pneumonitis can occur as larvae travel through the lungs. Epigastric pain, inflammatory diarrhea, and eosinophilia may develop with early intestinal invasion. Loss of plasma protein results from malabsorption and increased intestinal permeability and may cause anasarca.

Chronic hookworm infection leads to iron deficiency. In malnourished patients, infection can cause severe anemia and growth delay. Infection in pregnancy may lead to low fetal birth weights and birth defects. Pica and geophagy are observed in infected children.

Multiple stool specimens for ova and parasite studies or concentration techniques may be necessary to confirm the diagnosis. The parasite burden may be estimated using the Beaver stool or Kato 50 adult slide smear method. The polymerase chain reaction (PCR) technique can identify a hookworm from a single egg.

Hookworm infection may be confused with pneumonia, anemia, and malnutrition from other causes. Hypochromic microcytic anemia, coupled with eosinophilia or hypoproteinemia, indicates a heavy infection.
In addition to replication within the human host, Strongyloides can survive in a free-living cycle in soil. The rhabditiform larvae can directly transform into infective filariform larvae or a free-living soil form. The filariform larvae penetrate skin larvae are then swallowed and reach the small intestine. The host has no adult male worms, and the 2-mm female worms reproduce by parthenogenesis, hatching eggs within the intestinal mucosa. Rhabditiform larvae migrate to the intestinal lumen and either pass into the feces or directly transform into filariform larvae and cause autologous reinfection.

PRESENTING SIGNS AND SYMPTOMS

Patients may be asymptomatic or have mild abdominal discomfort, cough, dyspnea, wheezing, and peripheral eosinophilia. Ten percent of patients present with wheezing as their primary complaint. If adult worms invade the duodenojejunal mucosa, the symptoms can mimic those of peptic ulcer disease, and small bowel obstruction may occur.

Fluctuating eosinophilia is a common finding. Strongyloidiasis may also manifest with urticaria, usually recurrent along the buttocks and wrists. These urticarial serpiginous eruptions are called larva currens, and they are pathognomonic findings.

DIAGNOSIS AND MEDICAL DECISION MAKING

Stool examinations need to be repeated 3 to 5 times. An immunosorbent assay for aspiration or biopsy of duodenojejunal contents is also available. Serum immunoglobulin G (IgG) antibodies can be detected with enzyme-linked immunosorbent assay (ELISA). In disseminated strongyloidiasis, sputum, bronchoalveolar lavage samples, and surgical drainage fluids should be examined for larvae. Eosinophilia greater than 5% or a finding of more than 400 eosinophils/microliter is consistent with Strongyloides infection. Strongyloidiasis can mimic gastroenteritis, gastritis, colitis, irritable bowel syndrome, asthma, and pneumonia. It may also cause meningoitis or sepsis.

TREATMENT

Strongyloidiasis must be treated to avoid hyperinfection. In patients coinfected with human T-cell lymphotropic virus-1 (HTLV-1), treatment failures are common. A regimen of ivermectin plus thiabendazole or ivermectin plus albendazole is recommended for patients with disseminated disease.

INTESTINAL ROUNDWORMS: ENTEROBIS (PINWORMS)

Epidemiology

Enterobiasis is worldwide in distribution and is commonly found in young children. Pinworms are most common in developed countries with temperate or colder climates. The adult worms are 6 to 12 mm in length and 0.3 to 0.5 mm in diameter. The eggs are 50 by 25 mcm and are asymmetrically flattened on one side.
crypts. The adult worms live in the cecum and appendix and survive for approximately 2 months. Whether pinworms cause appendicitis is not known. The female pinworm migrates out through the rectum and onto the perianal skin to deposit her eggs. Rarely, the worms invade the abdominal cavity and cause threadworm granulomas of the liver, ovary, kidney, spleen, and lung. Transmission of pinworms occurs by direct anus-to-mouth spread from contact with an infected person. It can also be caused by airborne eggs that are shaken free from contaminated clothing or bed linens. Autoinfection is common because patients scratch the pruritic anal area and then bite their nails or put their fingers in their mouth. The whole cycle takes 2 to 4 weeks.

**PRESENTING SIGNS AND SYMPTOMS**

Pruritus ani is the main symptom and varies from mild itching to acute pain, generally worse at night. Pinworm disease is essentially an allergic reaction to the release of eggs and other secreted materials from the gravid female. Associated scratching and excoriation can cause secondary bacterial infection. Vulvitis can occur when pinworms enter the vulva and cause a mucoid discharge with pruritus vulvae. Insomnia, restlessness, loss of appetite, weight loss, irritability, and enuresis may be associated with pinworm infection.

**DIAGNOSIS AND MEDICAL DECISION MAKING**

The eggs are rarely seen in the feces, but they are observed when the adult worms migrate to the anus or vulvar area, particularly at night. The “Scotch tape test” is done by pressing a piece of clear sticky tape against the perianal region and then mounting the tape on a slide. The eggs are identified with light microscopy. Patients usually have no eosinophilia or associated anemia.

**TREATMENT**

The entire family is treated simultaneously, to avoid reinfec-
tion. All bedding and contaminated clothing should be washed. Fingernails should be kept short. Frequent hand washing and bathing may reduce reinfec-
tion. Eradication of the parasite may necessitate repeated courses of treatment.

**TISSUE NEMATODES: TRICHINELLA**

**EPIDEMIOLOGY**

Trichinosis has a worldwide distribution. Eight species of *Trichinella* infect humans. *Trichinella spiralis* and *Trichinella pseudospiralis* are found worldwide. *Trichinella nativa* is found in the Arctic; *Trichinella nelsoni* occurs in eastern Africa; *Trichinella britovi* is found in Europe, Asia, and western Africa; and *Trichinella murrelli* occurs in North America. *Trichinella papuae* and *Trichinella zimbabwensis* have also been identified. Human infection results from ingestion of poorly cooked infected meat, particularly pork. Cattle, horse, dog, and wild game meat are also potential sources.

**TRANSMISSION AND LIFE CYCLE**

The encysted larvae are released from their capsule by diges-
tive enzymes in the intestine. The larvae then penetrate the intestinal mucosa and mature into adults. After mating, the male worms die, and the female worms discharge larvae to the tissues. After travelling through the circulation, the larvae encyst in muscle and may calcify. Cysts can be seen in the diaphragm, masseter and intercostal muscles, musculature of the larynx, tongue, eye, and heart, and the brain.

The main methods of infection prevention are thorough cooking and regular meat inspection. *Trichinella* larvae in meat may be killed by heating to a temperature of 77° C or freezing to 15° C for 3 weeks. Both encysted and free *Trichinella* larvae remain viable for years.

**PRESENTING SIGNS AND SYMPTOMS**

The presenting symptoms depend on the level of infection and the location of the larvae. Two phases are recognized: intestinal and muscular. Enteric invasion may cause diarrhea, fever, nausea, vomiting, and abdominal pain during the first week of infection and is often confused with food poisoning. During the second week, the larvae migrate into the muscles and cause hypersensitivity reactions with fever, eosinophilia, rash, headache, cough, and myalgias.

Cardinal clinical findings of trichinellosis include cachexia, edema, splinter hemorrhages, dehydration, ongoing fever, and pruritus. Myocarditis, encephalitis, nephritis, congestive heart failure, pneumonitis, hemiplegia, severe pain, psychiatric disturbances, and epilepsy may develop and lead to death.

**DIAGNOSIS AND MEDICAL DECISION MAKING**

Eosinophilia is a hallmark of trichinellosis. No relationship exists between the level of eosinophilia and the clinical course of disease. Other laboratory manifestations of trichinosis include leukocytosis and elevated creatine phosphokinase, lactate dehydrogenase, and myokinase levels. The diagnosis is made by identification of larvae in blood or tissue. Serologic assays are available, including ELISA, indirect immunofluorescence, and latex agglutination. The circulating antibody can be detected by serologic tests between 2 and 4 weeks after infection. Immunofluorescence is positive 2 to 3 weeks after infection. If serologic test results are equivocal, larvae may be found in muscle by trichinoscopy. This procedure is performed during the muscular phase approximately 7 days from onset of symptoms with samples taken from the deltoid, biceps, gastrocnemius, or pectoralis major muscle.

Trichinosis resembles many conditions: typhoid, encepha-
ritis, myositis, and tetanus. Trichinosis may also be confused with collagen disorders such as periarteritis nodosa and rheumatoid arthritis.
## TREATMENT

For light infections, supportive therapy with analgesics, rest, and antipyretics usually suffices. Patients with severe hypersensitivity reactions such as myositis, myocarditis, and central nervous system (CNS) disease may benefit from corticosteroids tapered over 2 to 3 weeks. Corticosteroids are not indicated for mild disease because the use of these agents can increase the number of circulating larvae.

## TISSUE NEMATODES: FILARIA

### EPIDEMIOLOGY

Filarial nematodes are estimated to infect 170 million persons. Four main species cause most serious infections: *Wuchereria bancrofti*, *Brugia malayi*, *Onchocerca volvulus*, and *Loa loa*. *W. bancrofti* is found in Africa, South America, Asia, the Pacific islands, and the Caribbean. *Brugia* species are found mainly in Southeast Asia, Asia, and Indonesia.

### TRANSMISSION AND LIFE CYCLE

Mosquitoes transmit infective *Wuchereria* and *Brugia* larvae during a blood meal. *Onchocerca* and *Loa loa* larvae are carried by the black and tabanid flies, respectively. The larvae mature into adults that remain alive in the lymphatics or subcutaneous tissues for years. Microfilariae are produced by the adult worms, which are ingested by mosquitoes and develop into infective larvae over a period of weeks.

### PRESENTING SIGNS AND SYMPTOMS

Most infected persons remain asymptomatic, and few progress to acute or chronic disease. Common presentations include hydrocele, adenolymphangitis, microscopic hematuria and proteinuria, and lymphangiectasia. Acute adenolymphangitis is a form of retrograde lymphangitis accompanied with high fevers, lymphadenitis, and often thrombophlebitis.

*W. bancrofti* infection involves the genital lymphatics, and it often manifests with epididymitis and scrotal pain. Travelers to endemic regions may develop acute edema, urticaria, and local lymphadenitis, especially of the femoral, axillary, inguinal, or epitrochlear lymph nodes.

### DIAGNOSIS AND MEDICAL DECISION MAKING

Parasite detection is key for definitive diagnosis. Blood and hydrocele fluid may demonstrate microfilariae, although blood draws should be timed based on the periodicity of the endemic species suspected. ELISA and rapid-format immunochromatographic card tests are available for *W. bancrofti* antigens. In addition, PCR assays for *W. bancrofti* and *Brugia* DNA are available.

High-frequency ultrasound with Doppler imaging of the breast and scrotum may reveal dilated lymphatics containing moving adult worms, known as the filarial dance sign. The broad cross-reactivity of filarial antigens with other helminths often confounds the serologic test results. In addition, endemic populations may become sensitized through mosquito exposure without actual infection.

### TREATMENT

*Wolbachia* bacterial endosymbionts are present in most filarial worms, with the exception of *L. loa*. When patients are treated with diethylcarbamazine, a hypersensitivity reaction to the intracellular *Wolbachia* may occur and may progress to encephalopathy. Diehtylcarbamazine should not be used as treatment, except for *Loa loa*, because the hypersensitivity reaction can lead to hypotension or angioedema. Chemotherapy and vaccine development directed against *Wolbachia* are under investigation.

## TISSUE NEMATODES: ONCHOCERCA

### EPIDEMIOLOGY

*O. volvulus* is responsible for river blindness, a leading cause of infectious blindness in Africa, South America, and the Middle East.

### TRANSMISSION AND LIFE CYCLE

Blackfly vectors bite humans and transmit larvae into the skin. Nodules form in a few months to years, and the developed adults release microfilariae into the dermis. Adult worms can live for a decade or two.

### PRESENTING SIGNS AND SYMPTOMS

Onchocerciasis results from inflammatory reactions to the microfilaria that can affect skin, eyes, and lymph nodes. An intensely pruritic papular rash is common. Atrophy and pigmentation changes can occur in long-term infection. Subcutaneous nodules, or onchocercomas, contain adult worms and are common over bony prominences. Conjunctivitis, uveitis, chorioretinitis, and optic atrophy result from ongoing optic inflammation; neovascularization and scarring of the cornea lead to corneal opacity and eventual blindness. Lymphadenopathy is also common.

### DIAGNOSIS AND MEDICAL DECISION MAKING

The removal of an adult worm from onchocercomas or of microfilariae from skin snips leads to the definitive diagnosis. The Mazzotti test, involving a small dose of diethylcarbamazine (50 mg/kg) and subsequent observation for worsening rash or pruritus, can aid in diagnosis. Topical
diethylcarbamazine (10% in lotion) can be applied to the skin as a localized Mazotti test; it is considered safer than an oral test. If there are *Onchocerca microfilariae* present in the ocular chamber, diethylcarbamazine treatment can lead to ocular damage.

**Platyhelminthes**

(Flatworms)

The cestodes, or tapeworms, are segmented. Humans serve as intermediate hosts for *Taenia solium*, *Echinococcus*, *Hymenolepis*, *Sparganosis*, *Coenurus*, and *Dipylidiasis* species. *Taenia saginata* and *Dipyllobothrium* also can infect humans, although these species cannot complete their life cycle within human hosts. Tapeworm eggs are transmitted by the fecal-oral route and are endemic in areas with poor sanitation and livestock.

**CESTODE: TAENIA SOLIUM (PORK TAPEWORM)**

**EPIDEMIOLOGY**

*Taenia* has a worldwide distribution and is highly endemic in Latin America, Africa, Eastern Europe, Central and South Asia, and the Middle East. Approximately 45 *Taenia* species and subspecies are currently recognized. *T. solium* infection of the CNS, or neurocysticercosis, is a leading cause of acquired epilepsy and may result in more than 50,000 deaths annually.

The most distinctive feature of *Taenia* infection is that humans can serve as both the definitive host and the intermediate host. When humans are infected by the larval stage, the infection is known as cysticercosis. Infection with the adult tapeworm is associated with taeniasis. For *T. saginata* and *T. solium*, humans serve as the final obligatory host. Infection is uncommon in infants and vegetarians.

**TRANSMISSION AND LIFE CYCLE**

Humans acquire the infection by ingestion of undercooked pork containing cysticerci (larval cysts). The cysts contain protoscolices. After ingestion, the protoscolices are released and attach to the intestinal wall. Each protoscolex can become an adult tapeworm. The head of the worm generally resides in the jejunum. Adult worms contain 800 to 900 proglottids. Maturation occurs over 2 to 4 months. The mature proglottids are hermaphroditic, become gravid, and contain 1000 to 2000 eggs. These eggs are passed in the stool. Pigs acquire the infection from soil contaminated with human feces, and then larvae are activated, penetrate tissues, and encyst within 2 to 3 months.

**PRESENTING SIGNS AND SYMPTOMS**

Most patients are infected by a single worm. The symptoms are usually mild, or the patient may be asymptomatic. Because tapeworms can survive for years in an otherwise healthy host, symptomatic patients may have a protracted clinical course. Complaints are nonspecific and include indigestion, anorexia, diarrhea, constipation, and vague abdominal pain.

Severe signs and symptoms may include intestinal obstruction, appendicitis, and perforation. The worms occasionally migrate to the biliary system, respiratory tract, uterine cavity, or nasopharynx. If cysts are in the CNS, the patient may present with seizures, meningitis, stroke, or signs of increased intracranial pressure. Approximately 30% of patients with neurocysticercosis have residual calcification, and less than 20% have seizures. Parasite invasion of the ventricles can result in obstructive hydrocephalus. Extraparenchymal disease leads to a worse prognosis, secondary to invasive cyst growth and increased cerebrospinal fluid (CSF) debris and inflammation. Classic calcified lesions from prior infections are often seen on computed tomography (CT) or magnetic resonance imaging (MRI).

**DIAGNOSIS AND MEDICAL DECISION MAKING**

Infection is confirmed by finding the eggs or proglottids in the feces. The mobile proglottids often move with discharge, and some patients may feel their passage. Because the eggs are often eliminated intermittently, several stool specimens may need to be obtained. ELISA, DNA probes, and co-proantigen assays are available. The enzyme-linked immunoelectrotransfer blot (EITB) assay is quite specific and sensitive.

Neurocysticercosis is usually diagnosed by the characteristic CNS cystic lesions, which are nodular calcifications 5 to 20 mm in diameter, with or without ring enhancement on CT or MRI. Although calcified lesions are identified more easily on CT, MRI is more sensitive for ring enhancement and cystic lesions. The CSF may show pleocytosis, elevated protein, and occasionally low glucose concentrations.

**TREATMENT**

Calcified cysts do not warrant antiparasitic therapy. Patients with seizures may be treated with antiepileptics, and occasionally endoscopic surgery or ventriculoperitoneal shunting is necessary to relieve obstructive hydrocephalus. Corticosteroids may help mitigate cerebrovascular complications and may be used in the treatment of cysticercotic encephalitis.

**CESTODE: ECHINOCOCCUS**

**EPIDEMIOLOGY**

Echinococcosis is caused by the larval invasion of *Echinococcus granulosus*, *Echinococcus multilocularis*, and *Echinococcus vogeli*. These cestodes are ubiquitous, with...
CHAPTER 177: HELMINTHS, BEDBUGS, SCABIES, AND LICE INFECTIONS

particularly heavy endemicity in Central Asia, the Mediterranean, the Middle East, South America, and eastern Africa. *E. multilocularis* is confined to the Northern Hemisphere. *E. granulosus* causes cystic echinococcosis, with 3 million cases, and *E. multilocularis* is responsible for the alveolar variant, with half a million cases. Canines are the definitive hosts and pass echinococcal eggs in feces. Intermediate mammalian hosts then ingest the eggs, and eventually cysts develop. The cycle is continued as canines eat infected meat.

**TRANSMISSION AND LIFE CYCLE**

*E. granulosus* has three proglottids, one of which is gravid and releases eggs. After ingestion of the parasite, embryos penetrate the intestinal mucosa and enter the portal circulation. Fluid-filled hydatid cysts are formed in organs, commonly the lungs and liver. Within these hydatid cysts, brood capsules that house new larvae develop.

**PRESENTING SIGNS AND SYMPTOMS**

The cysts grow over several years, and patients are usually asymptomatic until large cyst size or encroachment causes abdominal pain, palpable masses, biliary colic, or, if in the lungs, dyspnea, cough, pleurisy, or hemoptysis. Cyst rupture may provoke an anaphylactic or allergic reaction with eosinophilia, fever, pruritus, and rash. Less commonly, the cysts can invade bone, CNS, cardiac tissue, and other intraabdominal structures.

**DIAGNOSIS AND MEDICAL DECISION MAKING**

Radiographs, CT, ultrasound, and MRI can all reveal cysts. Additional testing of aspirated fluids may reveal protoscolices. In addition, immunoblotting techniques are available for serologic antigen testing.

**TREATMENT**

Treatment depends on cyst size, location, and symptoms. Ultrasound staging is recommended. Percutaneous aspiration, infusion of scolicidal agents, and reaspiration (PAIR) is less invasive and is preferred over surgical removal. If cysts are superficial, honeycombed, connected to the biliary systems, or intrapulmonary, PAIR is not recommended. For complicated cysts, surgical intervention is warranted.

**CESTODE: DIPHYLLOBOTHRIUM (FISH TAPEWORM)**

**EPIEDEMILOGY**

*Diphyllobothrium* species are estimated to infect more than 20 million people. Although an overall decline in North America, Europe, and Asia has been reported, outbreaks have occurred in Russia, Japan, South Korea, Italy, France, Switzerland, and South America. *Diphyllobothrium* also enjoys a range of hosts, from humans to foxes, bears, sea birds, and other fish-eating mammals.

**TRANSMISSION AND LIFE CYCLE**

The fish tapeworm, or *Diphyllobothrium latum*, holds the dubious honor for longest tapeworm known to humankind, with adult worms measuring up to 10 to 25 m. The adult tapeworms consist of 3000 to 4000 proglottids and produce up to 1 million eggs a day; they may survive for decades in the human host. Egg-laden feces enter lakes, rivers, and deltas, and the eggs hatch into embryos. Crustaceans, usually *Cyclops* or *Diaptomus* species, ingest the free-swimming embryos, known as coracidia. The coracidia penetrate the crustacean intestinal wall and develop into a procercoid. The crustacean host is eaten by a freshwater or marine fish, and additional development takes place. The procercoid larva migrates into fish tissue and organs and develops into a proglolecid. The crustacean host is eaten by a freshwater or marine fish, and additional development takes place. The procercoid larva migrates into fish tissue and organs and sometimes cysts develop. The cysts grow over several years, and patients are usually asymptomatic until large cyst size or encroachment causes abdominal pain, palpable masses, biliary colic, or, if in the lungs, dyspnea, cough, pleurisy, or hemoptysis. Cyst rupture may provoke an anaphylactic or allergic reaction with eosinophilia, fever, pruritus, and rash. **TREATMENT**

Treatment depends on cyst size, location, and symptoms. Ultrasound staging is recommended. Percutaneous aspiration, infusion of scolicidal agents, and reaspiration (PAIR) is less invasive and is preferred over surgical removal. If cysts are superficial, honeycombed, connected to the biliary systems, or intrapulmonary, PAIR is not recommended. For complicated cysts, surgical intervention is warranted.
INFECTIONS

TREMATODA (FLUKES)

EPIDEMIOLOGY

Trematodes represent a diverse group of flatworms, or flukes, that cause human infection through invasion of blood, intestines, biliary system, and lungs. *Schistosoma* is perhaps the best known of the flukes. *Clonorchis* and *Opisthorchis* species cause biliary inflammation and obstruction and predispose patients to cholangiocarcinoma. *Paragonimus* and *Fasciolopsis* species cause granulomatous disease in the pulmonary and intestinal systems, respectively.

TRANSMISSION AND LIFE CYCLE

The life cycle of most trematodes involves a mammalian definitive host and intermediate snail hosts. Sexual reproduction occurs in the mammalian host, with subsequent asexual reproduction in snail hosts. Ova are excreted in feces or sputum, and they become miracidia that then undergo asexual reproduction in often multiple intermediate hosts. Free-living cercariae larvae and encysted metacercariae infect the definitive host. Transmission to humans is through ingestion or direct dermal penetration.

TREMATODA: SCHISTOSOMA

EPIDEMIOLOGY

Human schistosomiasis, also known as bilharziasis, remains a serious health threat in Africa, Southeast Asia, South America, and the Middle East. Schistosomiasis is a complex of acute and chronic parasitic infections caused by digenetic blood nematodes. Infections with *Schistosoma haematobium* (bladder fluke), *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma mekongi*, and *Schistosoma intercalatum* (intestinal flukes) cause illness in humans. Schistosomes have been documented to infect humans for thousands of years and are associated with agricultural civilizations of the great river valleys. Hematuria, most likely caused by *S. haematobium*, occurred in ancient Egypt and Mesopotamia.

TRANSMISSION AND LIFE CYCLE

The adult fluke lays eggs that leave the definitive host through the feces or urine, depending on the species and the host location. A freshwater species of snail is required as an intermediate host for each species of fluke. In general, the miracidium (larval stage) emerges from the egg in freshwater, enters the snail host, and then undergoes multiplication. The cercaria (final larval state) leaves the snail.

These larvae penetrate the tissues of humans through contact in infested freshwater. The cercaria then loses its tail, becomes a schistosomulum, and migrates to blood vessels to become an adult. Adults migrate into intestinal veins and vesical veins (*S. haematobium*) and lay eggs in the vasculature. The ova transmigrate through the lumen and are voided in feces or urine. Ova that reach freshwater complete the life cycle in intermediate hosts.

SIGNS AND SYMPTOMS

Patients may be asymptomatic initially, or they may show mild pruritic maculopapular skin lesions within hours to days after exposure to cercariae. Four to 8 weeks after invasion, some patients may present with fever, eosinophilia, lymphadenopathy, and hepatosplenomegaly. Acute schistosomiasis or Kato-yama fever resembles serum sickness, and it appears to be related to antigen excess during sexual maturation of the parasite. It is associated with a mortality rate of up to 25%.

Chronic schistosomiasis persisting for months to years after primary exposure is more common. A granulomatous reaction to *Schistosoma* eggs, coupled with host cell-mediated inflammatory response lead to organomegaly and obstruction. Patients may present with abdominal pain, hematemesis, ascites, hematuria, dysuria, vulvar or perianal lesions, dyspnea on exertion, fatigue, cough, chest pain, or seizures, depending on the site of infection and the involvement of the body system.

Eggs induce an immune response as they travel to the liver, intestine, bladder, and rarely, to the brain or spinal cord. Granuloma formation in the bowel wall with *S. mansoni* or *S. japonicum* may cause bloody diarrhea, cramping, and colonic polyposis. *Schistosoma* can also cause pulmonary and CNS disease, with sequelae including pulmonary hypertension, cor pulmonale, epilepsy, and transverse myelitis.

Egg retention and granuloma formation in the urinary tract with *S. haematobium* can lead to hematuria, urinary tract infections, glomerulonephritis, obstructive uropathy, dysuria, and bladder polyps and ulcerations. *S. haematobium* is considered a carcinogen in squamous cell bladder cancer.

DIAGNOSIS AND MEDICAL DECISION MAKING

Geographic history and clinical presentation are key considerations in diagnosing schistosomiasis. The diagnosis can also be aided by recovery of eggs in feces or urine, but Kato thick smear microscopy must be ordered specifically. Hatching assays on fresh stool specimens help to distinguish active from treated infection. Dead eggs may be shed for up to a year. Peripheral eosinophilia supports the diagnosis. Gross and microscopic hematuria is common in patients infected by *S. haematobium*.

Imaging techniques such as ultrasonography, echocardiography, and radiography can help pinpoint organ system involvement. ELISA testing is available and confirms past exposure, although it cannot discriminate between acute and chronic infection. The EITB test also yields good results. In some cases, colonic biopsy is necessary to visualize parasite eggs in the bowel wall.

Acute schistosomiasis should be suspected in patients recently returning from endemic areas who present with fever, headache, malaise, arthralgias or myalgias, bloody diarrhea, and right upper quadrant abdominal pain, especially if they have a history of freshwater swimming or bathing.
**BOX 177.2 Helminth Immunomodulation**

“The hygiene hypothesis suggests that microbes and worms are important for shaping and tuning the development and function of our immune system.”

As developed countries experience better sanitation and reduced exposure to infectious disease agents, the immune system may be left “uneducated” and may develop “incorrect” or uncontrolled inflammation responses: rhinitis, atopic dermatitis, asthma, inflammatory bowel disease, multiple sclerosis, and type 1 diabetes mellitus. Helminth infections as therapies have been observed to decrease colitis in both murine and human models. A few studies have shown benefit from *Trichuris* infection in patients with inflammatory bowel disease; similar results have been reported in patients with multiple sclerosis. Much more research is needed to characterize human-helminth immunomodulatory dynamics. Genetics and environment play important roles.

**TREATMENT**

Early treatment with cidal drugs may exacerbate Katayama fever, and concomitant steroid therapy is recommended. Patients with long-term infection may require procedures such as bladder stents, endoscopic treatment, or surgery.

Helminths cause a large burden of disease, yet their coevolution with humans and adaptation to our immune defenses may be beneficial (Box 177.2). Numerous epidemiologic and experimental studies have noted the low prevalence of allergy and autoimmune disease among populations with chronic helminth infections. Helminth infections generally cause a skewed type 1 helper T-cell (Th2) response. The Th1 arm of the immune system is often suppressed or down-regulated. Populations with chronic helminthiases may not clear microbial infections adequately or respond optimally to vaccination. *Schistosoma* and *Onchocerca* infections appear to decrease tetanus and tuberculosis vaccine efficacy, and *Ascaris* infection similarly dampens the immune response to *Mycoplasma* pneumonia vaccination.

**EPIDEMIOLOGY**

Bedbugs, or cimicids, are insects that have plagued humankind since ancient Egypt. These ectoparasites are found in temperate and tropical regions worldwide, and global infestations are increasing. Much media attention has been paid to bedbugs, and millions of dollars have been spent in the hospitality and private sectors. Travelers, backpackers, immigrants, guest workers, the homeless, and persons sharing close quarters, such as military barracks and dormitories, are potential hosts and vectors.

**TRANSMISSION AND LIFE CYCLE**

Cimicids are wingless, obligate hematophages. Both sexes require blood meals. *Cimex lectularius* and *Cimex hemipterus* are the two species that prefer human hosts. Adults are oval, flat, approximately 5 mm in length, and reddish brown. Adults can survive for up to 12 months, perhaps even 2 years, without feeding. Nymphs tend to be lighter in color. Bedbugs usually conceal themselves during the day, often in bedding, carpet, wallpaper, or any crevice, usually within 1 to 2 m of a host.

**PRESENTING SIGNS AND SYMPTOMS**

Most persons bitten by bedbugs are asymptomatic, perhaps bearing miniscule puncture wounds to exposed extremities, face, and neck. Those who seek medical attention commonly present with 2- to 5-mm puritic maculopapular, erythematous lesions at bite sites. If not excoriated or superinfected, these lesions resolve spontaneously within a week. Occasionally, some patients experience local popular rashes or diffuse urticaria. Bullous rashes, folliculitis, cellulitis, and eczematoid dermatitis may develop after a few days.

Anaphylaxis and asthma have also been reported, and they may be related to increased exposure with subsequent feedings. Saliva of bedbugs contains a protein, nitrophorin, that may be related to increased exposure with subsequent feedings. Beyond the physical irritation, bedbugs are responsible for anxiety, stigma, and insomnia.

**TREATMENT**

Topical antipruritics such as paroxime, doxepin, or corticosteroids may alleviate dermat irritation. Oral antibiotics may be necessary if lesions become secondarily infected by skin flora. For anaphylactic and urticarial reactions, supportive therapy including epinephrine, antihistamines, and corticosteroids is warranted. Much speculation remains about bedbugs as vectors for multiple diseases. Although human immunodeficiency virus (HIV) can be detected in bedbugs after a concentrated blood meal days later, no viral replication has been found, nor has virus been detected in the feces. Similarly, hepatitis B virus antigen has also been detected weeks after a feeding, but no internal replication has been observed. Concern about insecticide resistance is widespread.

**PATIENT TEACHING TIPS**

Inspect bedding carefully. Signs of bedbugs can be seen on infested mattresses and in bed frames.

Affected areas should be thoroughly cleaned. Bedding, infested furniture, and carpets should be placed in airtight plastic bags, steam cleaned, or thrown away.

Plastic mattress covers can be placed to prevent nocturnal emergence of the insects.
Scabies is a common parasitic infection caused by the mite Sarcoptes scabiei var. hominis, an arthropod of the order Acarina. Worldwide prevalence is estimated at 300 million. Scabies is endemic in sub-Saharan Africa, South and Central America, India, the South Pacific, and among Aboriginal communities in Australia. Additionally, infestations are sporadic in industrial countries. Overcrowding, poor hygiene and poverty, war, and dementia are predisposing factors. Despite the stigma of scabies as an infection of the poor, scabies affects all ethnic and socioeconomic groups.

**TRANSMISSION AND LIFE CYCLE**

These obligate parasites complete their entire life cycle on humans. Scabies mites measure 0.2 to 0.5 mm in length, naked to the human eye. Only the female mite burrows into the skin, where the mite tunnels at a rate of 2 mm/day. The parasite can survive approximately 36 hours away from the human host. Each mite lays approximately 10 to 25 eggs and then dies in the stratum granulosum. Larvae hatch in 3 to 4 days, molt, then leave the burrow for the surface, copulate, and continue the cycle. Maturation is complete in 15 days.

The number of mites infesting a person usually ranges from 5 to 15, although thousands may be present in patients with crusted scabies. Symptoms of infestation usually manifest 3 to 6 weeks after the mite is acquired, but they may appear as soon as 1 day after the mite is acquired in cases of reinfestation, as a result of a hypersensitivity reaction. The primary mode of transmission is direct skin-to-skin contact. Investigators estimate that a 15- to 20-minute encounter is sufficient to transmit the mite. Transmission through shared clothing or other objects is rare, but it may occur with crusted scabies. Mites crawl at a rate of 2.5 cm/minute on human skin. The greater the parasite load, the greater is the chance of transmission. Sexual transmission also occurs. Immunocompromised hosts, including those who are HIV positive, HTLV-1 positive, undergoing immunosuppressant therapies, and malnourished, are at higher risk for developing crusted (Norwegian) scabies.

**SIGNS AND SYMPTOMS**

Intense, intractable, pruritic dermatitis with erythematous papulovesicular lesions characterize scabies infections. The itch is usually worse at night or after a hot shower. Skin burrows, gray serpiginous lines 1 to 10 mm in length, are pathognomonic findings. In adults, burrows and nodules are usually found in interdigital web spaces, axillary folds, extremities, buttocks, nipples, and genitals. Very young children and immunocompromised persons may have facial and neck lesions. Lesions to palms and soles, pinkish brown nodules, and acral pustules are unique to infested infants.

Crusted, or Norwegian, scabies is usually confined to immunocompromised, older, cognitively impaired, and institutionalized patients. Presumably, the lack of scratching may allow superinfection to occur. Crusted scabies represents a hyperinfection with thousands to millions of mites present. The lesions appear hyperkeratotic, similar to psoriatic papules, and can cover large areas of the scalp, face, neck, and extremities. Skin crusts may be loose or adherent, flaky or thick. Nail involvement is common with crusted scabies, as are eczemization and impetigo. Large flakes of epidermis slough off, carrying mites and furthering transmission. In crusted scabies, high levels of IgE and IgG and peripheral eosinophilia are present.

Nodular scabies manifests with pruritic, violaceous nodules localized to the groin, axilla, and male genitalia. These nodules may represent a variant hypersensitivity reaction because mites are not found within them. Rarely, bullous lesions may occur with scabies, perhaps because of superinfection with Staphylococcus. Pyoderma, or bacterial skin infections, may be secondary to scabies infections, especially in the tropics.

**DIAGNOSIS AND MEDICAL DECISION MAKING**

The diagnosis is primarily clinical. Patients complain of generalized and intense pruritus, usually sparing the face and head. Symptoms are often out of proportion to examination findings. The definitive diagnosis is made by identification of mites, eggs, or mite fecaliths on microscopic evaluation of burrow scrapings. Obtaining multiple superficial skin samples from characteristic lesions is helpful. This is done by gently scraping laterally across the skin with a scalpel. If the number of mites is low, as is commonly the case in classic scabies, mites may not be identified. Skin biopsy may also be performed.

Enhanced microscopy techniques, such as epiluminescence microscopy and noncomputed dermoscopy, may also identify scabies products in burrows. ELISA and PCR assays can also aid in detection of scabies antibodies and help in determining the efficacy of treatment.

Scabies may mimic several diseases, including bullous pemphigoid, urticaria, chronic lymphocytic leukemia, B-cell lymphoma, necrotizing vasculitis, lupus erythematosus, secondary syphilis, atopic dermatitis, and urticaria pigmentosa.

**TREATMENT**

Empiric treatment is not recommended in the absence of a history of prolonged skin-to-skin exposure, typical eruption, or both. The infested patient and close physical contacts should be treated simultaneously, regardless of whether symptoms are present. Crusted scabies is very easily transmitted, and patients who have been even minimally exposed should be treated. Crusted scabies requires hospital admission, and keratolytics improve penetrance of topical therapy.
penetration. Usually, at least three consecutive topical treatments are required. Pruritus normally persists after treatment and may worsen as release of mite antigens exacerbates the hypersensitivity reaction. Most recurrent cases can be traced to untreated contacts.

### TRANSMISSION AND PATHOPHYSIOLOGY

_Pediculus_ species carry out their entire life cycle on the human host and survive only briefly in the environment. One female head louse can lay up to 150 eggs during her 1-month life span. Eggs (nits) are cemented onto hair shafts of the host and hatch in 1 week; full maturation to adult stages is completed in another week. If nits are found less than 1 cm from the scalp, an active infestation is considered highly likely. Because human hair grows at a rate of 1 cm/month, and nits can remain attached to hair for up to 6 months, the presence of nits a few centimeters from the scalp may not represent an active infestation. Lice are transferred directly from host to host. Eggs are transferred from louse-infested clothing or personal articles such as shared combs, head-phones, beds, and hats. Head lice can live up to 55 hours without a host.

### PRESENTING SIGNS AND SYMPTOMS

Signs and symptoms may include pruritus and pruritic papules at the site of infestation, especially in occipital and retroauricular regions. Saliva and fecal excretions of the louse may cause a local hypersensitivity reaction including fever, conjunctivitis, malaise, cervical lymphadenopathy, and a rash, mimicking a viral exanthem. If a secondary bacterial infection occurs, the lesion may resemble mange. Patients often identify the presence of a parasite before they present for treatment.

### DIAGNOSIS AND MEDICAL DECISION MAKING

The diagnosis is made by identifying lice or nits on the patient. Using a fine-toothed comb and placing any removed lice or nits on a light-colored surface and viewing them with a magnifying device may assist in the identification. The head louse is a gray-white, 3- to 4-mm insect. Currently, no antibody or serologic tests exist. The diagnosis is based on clinical suspicion, with confirmation on finding _Pediculus_ adults, nymphs, or nits.

### TREATMENT

Three main avenues exist for treatment: mechanical removal, topical agents, and oral therapy (Table 177.1). Children can return to school immediately after completion of the first application of a topical insecticide. Wet hair combing to remove _P. humanus capitis_ nits and adults is not as effective as the use of topical agents. Infested clothing and bed linen should be washed in hot water, dry cleaned, or discarded.

---

**Scabies** is a benign, easily treated disease commonly called “the itch.”

- It causes a pruritic rash and spreads rapidly among people in close proximity.
- Transmission among family members and within institutional settings is common.
- Itching can persist for up to 4 to 6 weeks after the completion of treatment.
- Schools do not ordinarily provide the level of contact necessary for transmission.
- Keep fingernails well trimmed!

REFERENCES

Tetanus is a rare disease in the United States, with only 20 cases reported in 2003. In 1990 to 2000, the average number of cases in the United States was 50 per year. The average annual incidence from 1995 to 2000 was approximately 0.16 cases per million population.\(^1\) Tetanus is more common among people 60 years old or older (0.35 cases per million population), patients 60 years old or older who have diabetes (0.70 cases per million population), and Hispanic persons (0.37 cases per million population). Injecting drug users are at unique risk for tetanus and accounted for 15% of cases of tetanus from 1998 to 2000.\(^1\) Most (74%) injecting drug users who developed tetanus reported injecting heroin, and 100% reported “skin popping” rather than intravenous injection.\(^5\)

Tetanus morbidity and mortality remain high, even with appropriate treatment. Current vaccination status decreases the severity of the disease and the likelihood of death from tetanus. In 1998 to 2000, 18% of patients with tetanus died. Of fatal cases, 75% occurred in patients who were 60 years old or older. No patients with an up-to-date vaccination status died of tetanus.\(^7\)

providers should also consider a patient’s pertussis immunization status when choosing the tetanus vaccine.

## ANATOMY

Most cases of tetanus are associated with acute trauma (Table 178.1), but many cases are associated with abscesses, cellulitis, chronic ulcers, dental infections, frostbite, and gangrene. In one study of injecting drug users with tetanus, 69% had an abscess at the injection site. Tetanus affects postpartum women, with an increased risk after unsanitary birth or abortion practices. Puncture wounds are the most frequent type of acute trauma associated with tetanus. Puncture wounds include nail injuries to the foot, splinters, barbed wire injuries, tattoos, drug injection, penetrating eye injuries, and spider bites. Crush injuries, burns, and eye injuries are also portals of tetanus infection. In patients with tetanus, approximately 50% of injuries are located on the lower extremity, 36% on the upper extremity, 10% on the head or trunk, and 5% on other areas. The occurrence of tetanus following minor or trivial wounds is well documented in the literature. Tetanus results from minor wounds and abrasions when proper wound care is not administered. Nearly half of the wounds that resulted in tetanus in 1998 to 2000 occurred indoors.

## PATHOPHYSIOLOGY

Clinical tetanus is caused by two exotoxins produced by Clostridium tetani, a gram-positive, anaerobic rod. The bacterium produces spores that are heat resistant, surviving autoclaving at 250° F for 10 to 15 minutes, and resistant to treatment with phenols and common chemical agents. The bacterium dies with heat or oxygen exposure. The bacterium and spores are widely disseminated in soil, intestines of farm animals and pets, and feces. Spores exist on human skin and contaminated heroin. In anaerobic conditions, such as puncture wounds and crush injuries, spores germinate. Tetanus becomes a systemic disease as the toxin spreads through the body. Tetanospsamin binds to nerve terminals, is internalized, and travels in retrograde fashion to the cell synapse. The toxin travels at 75 to 250 mm/day, and it affects synapses of shorter nerves before synapses of longer nerves. The toxin also travels by lymphatic and blood flow to remote nerves. The toxin exhibits local effects first and then spinal motor effects. The autonomic system is the last to be affected because of the length of the nerves. Tetanospsamin also inhibits acetylcholine release, a process that leads to flaccid paralysis between episodes of spasticity.

C. tetani enters the body through a wound and produces two exotoxins: tetanolysin and tetanospsamin. Tetanolysin causes local cell death and creates an anaerobic environment in the wound site. Tetanospsamin interferes with the transmission of inhibitory impulses in the central nervous system. It creates a presynaptic blockage of the inhibitory Renshaw cells and la fibers of alpha motoneurons that transmit gamma-aminobutyric acid (GABA) and glycine. Renshaw cells that transmit acetylcholine are not affected as strongly. Tetanospsamin binding prevents inhibitory signals in the central nervous system.

Tetanus becomes a systemic disease as the toxin spreads through the body. Tetanospsamin binds to nerve terminals, is internalized, and travels in retrograde fashion to the cell synapse. The toxin travels at 75 to 250 mm/day, and it affects synapses of shorter nerves before synapses of longer nerves. The toxin also travels by lymphatic and blood flow to remote nerves. The toxin exhibits local effects first and then spinal motor effects. The autonomic system is the last to be affected because of the length of the nerves. Tetanospsamin also inhibits acetylcholine release, a process that leads to flaccid paralysis between episodes of spasticity.

The result of the general loss of inhibitory signals is rigidity with periods of spasticity. The reflex inhibition of antagonizing muscles is lost, thus allowing agonist and antagonist muscle groups to contract simultaneously. Autonomic disinhibition occurs late in the disease. Toxin binding appears to be irreversible; the growth of new nerve terminals is required to overcome the effects.

## CLINICAL PRESENTATION

The average incubation period from time of injury to the onset of symptoms is 7 to 10 days, with a range of 1 to 60 days. Shorter incubation times are associated with more severe clinical presentation and a poor prognosis. Tetanus is usually an afebrile disease until autonomic instability occurs late in the disease. Fever suggests coinfection of the wound or other infectious causes. Generalized tetanus, or tetanus affecting the whole body, is the most common form of tetanus.
In the first week of illness, the patient presents with rigidity and muscle spasms. Tetanus most commonly affects the cranial nerves first. The most common first symptoms and signs are trismus, neck stiffness, and dysphagia. Muscle spasm progresses diffusely to involve the facial muscles, thus causing the classic facial grimec risus sardonicus. Disinhibition of the neck muscles causes neck extension. Truncal rigidity follows head and neck involvement.

The general increased tone is interrupted by acute spastic events that can involve any muscle groups. These spastic events can be spontaneous or caused by tactile, visual, or auditory stimuli. Agonist and antagonist muscle groups can simultaneously contract. The contractions are painful and can be strong enough to break long bones and avulse tendons. Opisthotonos is a classic spastic event in tetanus. Abdominal rigidity can mimic an acute abdomen. Spasticity of the trunk and diaphragm can interfere with respiration. Laryngeal spasm interferes with the gag reflex or can occlude the airway.

Before modern mechanical ventilation, death resulted from respiratory failure or aspiration. With modern mechanical ventilation, death is more commonly caused by autonomic events.

The second week of illness involves autonomic instability in addition to the muscle spasms. The sympathetic nervous system is more strongly affected. Sudden increased autonomic tone, with elevated circulating catecholamine levels, increased vascular tone, hypertension, and tachycardia alternate with profound hypotension, bradycardia, and even cardiac arrest. Cardiac dysrhythmias occur, and the patient may develop hyperpyrexia at this point.

Recovery begins in the third or fourth week. Muscle spasms decrease, but rigidity may persist. The duration of recovery, in those who survive, ranges from 2 to 4 months, as new axon terminals grow. Most patients return to their baseline with no residual deficit.

**VARIATIONS**

Local tetanus is an uncommon presentation of the disease in which only focal symptoms occur. Muscle spasticity is limited to the area adjacent to the wound. Local tetanus can progress to generalized tetanus, and the disease is generally milder. The exception is in cases of cephalic tetanus.

Cephalic tetanus is another rare form of disease. Cephalic tetanus follows a head or facial wound or, rarely, otitis media. The cranial nerves are initially affected. Spasticity or flaccid paralysis may be the presentation. Cephalic tetanus generally progresses rapidly to generalized tetanus and is associated with a severe course.

Neonatal tetanus is generalized tetanus of the neonate. It occurs in infants born to mothers who are inadequately immunized. The port of entry is usually the umbilicus, with increased risk if the umbilicus is cut with a nonsterile instrument or is packed with contaminated material, such as soil, dung, or clay. Symptoms manifest on day 3 to 9 of life.

The initial presentation is failure to feed in a child who previously fed normally. Neonatal tetanus progresses to generalized tetanus as described previously. The mortality rate of neonatal tetanus, when treated, is 25% to 90%. Thirteen cases of neonatal tetanus were diagnosed in the United States from 1992 to 2000. In these cases, 85% of the neonates had not been vaccinated because of parental religious or philosophic objections.

**DIAGNOSTIC TESTING**

The diagnosis of tetanus is clinical. The *Vaccine-Preventable Diseases Surveillance Manual* defines tetanus as “the acute onset of hypertonia or by painful muscular contraction (usually, initially of the jaw and neck) and generalized muscle spasms without other apparent medical cause.” No laboratory tests confirm or refute the diagnosis of tetanus. The organism is rarely recovered from wounds and can be cultured from patients without clinical tetanus. Serologic testing to detect anti-tetanus antibody levels plays a small role in the diagnosis of the disease. Patients can develop tetanus with “protective” levels of antibody. The aim of testing is to rule out other causes of rigidity and spasticity. If tetanus is suspected, begin treatment immediately. Do not delay treatment, because no confirmatory test exists.

Check the patient’s electrolytes, primarily to evaluate for hypocalcemia. Order a strychnine level determination if concern exists about exposure to strychnine, with the understanding that illegally imported pesticides contain strychnine. Ask patients about pesticide exposure, and consider accidental ingestion in children.

Obtain a computed tomography scan of the head if an acute intracranial event is considered. A lumbar puncture is necessary only if meningitis or encephalitis is included in the differential diagnosis. Examination of cerebrospinal fluid is

---

- Intracranial hemorrhage
- Rabies
- Bell palsy
- Ischemic stroke

Because tetanus is a rare disease in the United States, it is difficult to suspect and diagnose. Tetanus should be considered in the differential diagnosis of patients with rigidity or spasticity. The disease can be found in the setting of a minor or trivial injury that may not be remembered by the patient or family. Tetanus is more common in patients without vaccination or without booster in the last 10 years. Unusually, from 1998 to 2000, 6% of tetanus cases occurred in patients who reported being up to date on tetanus vaccination.

Older patients and patients with chronic illness may have a decreased immune response to vaccination and therefore may lack protective antibody levels to tetanus in spite of appropriate vaccination. This situation is increasingly true in patients aged 65 years or older.
noncontributory in tetanus, except to rule out other disorders. Because of unpredictable muscle spasms, performance of lumbar puncture on a patient with generalized tetanus may require intubation and deep sedation or muscle relaxation.

The spatula test has been used to distinguish tetanus from other forms of spasticity. In this test, a blunt instrument such as a tongue blade is used to touch the oropharynx. A patient without tetanus gags and attempts to expel the instrument. In a patient with tetanus, the stimulus triggers masseter spasm, resulting in a reflex bite of the blade. Although this test is reported to have a sensitivity of 94% and a specificity of 100%, the results may not be applicable to the United States, where tetanus is rare.

MANAGEMENT

Management of tetanus has two aspects: prevention and treatment. Each time an EP sees a patient with a wound, the opportunity for prevention exists. Treatment of tetanus is multifaceted and includes systemic treatment of the toxin, supportive treatment of the muscle spasms, and wound care.

PRIORITY ACTIONS

Suspect tetanus in patients with rigidity.
- Control airway and ventilation.
- Administer tetanus immune globulin.
- Administer antibiotics.
- Aggressively treat spasticity.
- Débride wounds and incise abscesses.

PREVENTION

Prevention through vaccination and proper wound care remains the mainstay of therapy for tetanus. Update the patient’s tetanus immunization, and administer tetanus immune globulin according to Centers for Disease Control and Prevention guidelines (Fig. 178.1). Maintain the patient’s current tetanus immunization status in cases of cellulitis, abscesses, eye injuries, chronic ulcers, burns, injecting drugs, minor abrasions, acute lacerations, punctures, and crush injuries (Figs. 178.2 to 178.4). Clean wounds to remove any contaminants.

Some patients have decrease in tetanus titers earlier than 10 years. For this reason, patients with wounds that are not clean or are more than minor should receive a tetanus booster at 5 years after the last booster. Clinical tetanus does not confer immunity. Therefore, survivors of tetanus require immunization when they are clinically stable. Pregnant women can receive tetanus prophylaxis, if indicated. No confirmed risk to the fetus has been determined from tetanus-diphtheria or tetanus immune globulin.

TREATMENT

Antitoxin Therapy

Administer tetanus immune globulin at a dose of 3000 to 5000 units intramuscularly to the pediatric or adult patient. Some sources recommend infiltration of some immune globulin around the wound site, if identified. Intravenous immune globulin has tetanus antitoxin and may be administered if tetanus immune globulin is not available in a reasonable amount of time.

Antibiotic Therapy

Metronidazole is the drug of choice for tetanus. Administer intravenously, 1 g every 12 hours or 500 mg every 6 hours, to adult patients. Administer intravenous metronidazole at 30 mg/kg/day, divided every 8 or 12 hours, to pediatric patients. Penicillin G is the second choice of antibiotics. Penicillin antagonizes GABA with unknown clinical significance. The dose of penicillin is 24 million units intravenously,
divided every 4 to 6 hours, for adults. The pediatric dose of penicillin G is 100,000 to 250,000 units/kg/day, divided every 6 hours.\textsuperscript{39-43} Erythromycin, doxycycline, tetracycline, chloramphenicol, and clindamycin are alternatives if metronidazole and penicillin are contraindicated.\textsuperscript{43,44}

**Supportive Therapy**

Muscle spasms are controlled with large doses of benzodiazepines to augment GABA activity. Continuous infusions improve effectiveness. Control pain with generous doses of morphine or another opiate, but avoid meperidine. If

---

**Fig. 178.1**  Approach to tetanus prevention. CDC, Centers for Disease Control and Prevention; TIG, tetanus immune globulin.

**Fig. 178.2**  Chronic ulcers, especially in diabetic patients, pose an increased risk for tetanus.

**Fig. 178.3**  Even subtle abrasions and puncture wounds present an increased risk for tetanus.

**Fig. 178.4**  A puncture wound to the hand from this organic material introduces a significant tetanus inoculum.
respiratory depression results from sedation, intubate the patient. Magnesium in a continuous intravenous infusion has been used as an adjunct to benzodiazepines in the treatment of muscle spasms. Magnesium contributes to respiratory depression.48,51 Sedation with propofol at levels equivalent to those used during general anesthesia decreases muscle rigidity and spasm. Intubate the patient before using propofol.48,50

Closely monitor the patient’s respiration, ventilation, and airway reflexes. Intubate patients with any sign of respiratory or ventilatory compromise resulting from truncal or laryngeal spasm.

If deep sedation with benzodiazepines and opioids fails to control muscle spasm, intubate the patient. Intrathecal baclofen has been used with success in a few patients. The large doses of baclofen required result in respiratory depression and coma that necessitate intubation in many patients.48,50 If intrathecal baclofen is not available on an emergency basis or if it fails to produce an improvement, administer a neuromuscular blocking muscle agent.

Patients with tetanus are at increased risk of aspiration because of the loss of laryngeal reflexes, atony of the stomach, and forceful contraction of the abdominal wall. Empty the patient’s stomach to decrease the chances of aspiration.

Autonomic instability is a late finding and is not likely to be treated in the ED. Sedation with morphine and maintenance of a quiet, low-stimulus environment are critical in decreasing autonomic instability.48,51,52 Esmolol has been used to control hyperadrenergic states. Propranolol and labetalol are both linked to increased mortality.52,53

**Wound Therapy**

Débride necrotic wounds with wide margins, to remove the anaerobic environment and to arrest *C. tetani*. Incise and drain abscesses. Débride necrotic tissue at abscess sites. Do not delay débridement or incision and drainage. Perform these procedures on an emergency basis.

**PATIENT TEACHING TIPS**

Inform all patients of the risk of tetanus for even minor, clean wounds.

Recommend routine immunization every 10 years, even without injury.

Encourage patients to record tetanus boosters in their own records and to notify their primary care doctor of vaccination boosters.

Update tetanus immunization before pregnancy and childbirth.

The tetanus-diphtheria booster is believed to be safe in pregnancy and is given if an acute indication exists.

REFERENCES

Rabies is transmitted when saliva or neural tissue from an infected host contacts open wounds or mucous membranes of a recipient. This transmission can occur through bites, aerosolized tissue, or tissue transplantation. Rabies virus is not transmitted by blood, feces, or urine. Rabies is not transmitted across intact skin.

Once the virus is in a new host, it performs one of two actions. Some virus replicates at the site of the bite in non-nerve tissue. The virus then enters peripheral nerves and travels to the central nervous system (CNS). Some virus does not replicate at the site, but rather immediately enters the peripheral motor and sensory nerves for transport to the CNS. During this time, the virus is in an eclipse phase, and it is difficult to detect with diagnostic tests. The virus travels at speeds of 15 to 100 mm/day by retrograde axoplasmic flow.

When the virus enters the CNS, the incubation time ends. Incubation times range from 2 weeks to several years, and the average is 2 to 3 months. Once in the CNS, the virus replicates and spreads by cell-to-cell transfer. The virus then travels by anterograde axoplasmic flow to nervous and non-nervous tissue. At the onset of clinical symptoms, the virus is disseminated throughout the body.

**ANATOMY**

Rabies is caused by a negative-stranded RNA virus that belongs to the Lyssavirus family. The virus envelope fuses to the host cell membrane, and the virion penetrates the cell, where it replicates and buds new virus.

The virus causes inflammation in the CNS, both encephalitis and myelitis. Perivascular lymphocytic infiltration occurs with lymphocytes, polymorphonuclear leukocytes, and plasma cells. Cytoplasmic eosinophilic inclusion regions (Negri bodies) in neuronal cells are associated with rabies, but they are not sensitive or specific for the diagnosis of rabies. Viral replication in dorsal root ganglia causes ganglionitis, and it is responsible for the first clinical symptoms of the disease.

**CLINICAL PRESENTATION**

The first clinical symptoms of rabies are neuropathic pain, paresthesias, or pruritus at the inoculation site. These symptoms are followed by fever, malaise, headache, and photophobia. The incubation period is variable, ranging from 2 days to several months.

**PATHOPHYSIOLOGY**

Rabies is a fatal disease. Only 6 people are known to have survived the disease. The low rate of occurrence of the disease challenges physicians to consider this in the differential diagnosis of encephalitides.

Postexposure prophylaxis, if started before clinical signs of rabies develop, is highly effective. With strict adherence to protocol, including wound care, passive immunization, and vaccination with a cell culture vaccine, postexposure prophylaxis prevents rabies. Emergency physicians (EPs) should know when to begin rabies postexposure prophylaxis, when to delay it, and when postexposure prophylaxis is not indicated, and they should also know state and local resources for rabies information.
The furious form of rabies is rapidly progressive and is fatal in 1 to 5 days (Table 179.1). The paralytic form of rabies is more slowly progressive, and patients live for up to a month. However, clinical rabies is considered a fatal disease regardless of the clinical manifestation.

In the early stage of the disease, tests may show negative results. The “gold standard” for the diagnosis of rabies is direct fluorescent antibody testing of the brain. Brain biopsy exclusively for the diagnosis of rabies is discouraged.

Multiple testing techniques exist for the diagnosis of rabies during life. Discuss with the pathologist the preferred sample at your institution. Serum, saliva, and skin samples are commonly used, whereas cerebrospinal fluid, urine, and lacrimal fluid are occasionally tested. Do not withhold empiric antirabies therapy to obtain diagnostic studies.

Perform a lumbar puncture for analysis of cerebrospinal fluid for meningitis and encephalitis. Sedate the patient, if necessary, to control spasms. Send cerebrospinal fluid for diagnostic studies according to the patient’s geographic exposure. Perform a toxicologic screen to evaluate for intoxication, but remember that intoxicants may be incidental findings.
RABIES TRANSMISSION

Rabies is transmitted only by mammals, both domestic and wild. Common wild animals known to contract and transmit rabies include foxes, skunks, raccoons, coyotes, and bats. Dogs, cats, cattle, and other domestic animals can also contract and transmit rabies.

Patients commonly present after bites and scratches from small rodents, both wild and domestic. In these circumstances, wound care and reassurance are all that is required. Rats, mice, squirrels, chipmunks, hamsters, and guinea pigs do not transmit rabies. Rabbits and other lagomorphs have not been found to have rabies and have never been known to cause rabies.

Postexposure prophylaxis is virtually never indicated after a bite from or exposure to any rodent, so the health department should be consulted before initiating postexposure prophylaxis if the animal’s behavior was suspicious and prophylaxis appears clinically indicated.

To assess the likelihood of rabies exposure, it is helpful to know the distribution of rabid animals in the area. The local or state health department can provide information about rabies prevalence and animal vectors. A list of state health department contact numbers is available through the Centers for Disease Control and Prevention (CDC) at http://www.cdc.gov/ncidod/dvrd/rabies/professional/profess.htm. Moreover, the CDC can be contacted at 877-554-4625 after hours or if the local or state health department is unavailable (http://www.cdc.gov/ncidod/dvrd/rabies/Links/Links.htm). Moreover, the CDC can be contacted at 877-554-4625 after hours or if the local or state health department is unavailable (http://www.cdc.gov/ncidod/dvrd/rabies/professional/professi.htm).

If the animal involved can carry rabies, determine whether the patient had an exposure (see the “Facts and Formulas” box). Consider any breach in the skin that was caused by teeth to be a bite exposure. Exposure to aerosolized virus in a laboratory or cave setting constitutes a nonbite exposure. Saliva, neural tissue, or other infectious material contacting open wounds or mucous membranes constitutes an exposure. Contact of infectious material with intact skin does not constitute an exposure, nor does contact with noninfectious material, such as feces, blood, or urine, or petting a rabid animal. Do not provide postexposure prophylaxis to patients who have not had an exposure.

If an exposure has occurred, the decision to begin postexposure prophylaxis is multifactorial. The type of animal, the epidemiology of rabies in the region of the exposure, and the

**TIPS AND TRICKS**

**Postexposure Prophylaxis**

**Status**

Unvaccinated

Postexposure Prophylaxis Regimen

Wash the wound thoroughly with soap and water.

Treat the wound with a virucidal agent (povidone-iodine).

Administer RIG, 20 units/kg. Infiltrate as much as possible into wound and tissue immediately adjacent to the wound. Administer the remaining dose intramuscularly, remote from the tetanus vaccination site.

Administer 1 mL tetanus vaccine intramuscularly. Use the deltoid muscle in adults. Use the deltoid or anterior thigh in small children. Avoid the site of RIG administration.

Instruct the patient to receive four more vaccinations, on days 3, 7, 14, and 28.

Previously vaccinated

Wash the wound thoroughly with soap and water.

Treat the wound with a virucidal agent (povidone-iodine).

Do not administer RIG.

Administer 1 mL tetanus vaccine intramuscularly. Use the deltoid muscle in adults. Use the deltoid or anterior thigh in small children.

Instruct the patient to receive one more vaccination, on day 3.

RIG, Rabies immune globulin.
postexposure prophylaxis immediately (see the “Tips and Tricks: Postexposure Prophylaxis” box). If a wild animal responsible for an exposure is caught, it should be immediately and humanely euthanized and tested. Wild animals should never be observed for signs of rabies because the time course of rabies in mammals other than dogs, ferrets, cats, and humans is not understood. If a wild animal that is a potential vector for rabies is responsible for an exposure but is unable to be captured, begin

health of the animal all contribute to the decision. Figure 179.1 provides an algorithm for the decision to start postexposure prophylaxis in humans. If an exposure involved a wild animal of a species that is a rabies vector, in a rabies-endemic area, begin postexposure prophylaxis immediately (see the “Tips and Tricks: Postexposure Prophylaxis” box). Do not await laboratory results. If the animal involved is an unlikely vector, postexposure prophylaxis can be withheld in consultation with the health department or CDC, as long as the animal can be tested for rabies, with results available within 48 hours.

If a wild animal that is a potential vector for rabies is responsible for an exposure but is unable to be captured, begin
prophylaxis on all bites, scratches, and mucous membrane exposures to bats. Strongly consider postexposure prophylaxis in anyone who has had contact with a bat, even people who may be unaware of injury.2 Strongly consider postexposure prophylaxis in a person who is near a bat and is uncertain whether contact has occurred, such as a person who awakens in a room with a bat.24

If the animal responsible for an exposure is a pet cat, dog, or ferret that is not currently showing signs of rabies, the animal can be observed for 10 days under the care of a veterinarian.25,26 A currently vaccinated dog or cat is unlikely to have rabies, but vaccination failures have been reported. Therefore, even vaccinated animals should be reported to the health department for observation.6

If the animal remains healthy, postexposure prophylaxis need not be started. If any suspicion exists that the animal is rabid, begin postexposure prophylaxis (see the “Tips and Tricks: Postexposure Prophylaxis” box). Postexposure prophylaxis can be terminated if laboratory results show that the animal does not have rabies. If the domestic animal is not identifiable, contact the local health department to determine whether postexposure prophylaxis is indicated in your area.

In the case of a healthy, known pet that is not suspected of having rabies, provide the patient with information regarding the local health department and the need for animal quarantine by local animal control. The patient bears the responsibility of maintaining contact with the health department and animal control regarding the status of the animal. EEs are not expected to perform these functions for the patient. The CDC considers postexposure prophylaxis a medical urgency, not an emergency. Therefore, it is reasonable, in the low-risk exposures outlined in Figure 179.1, to delay postexposure prophylaxis. In this case, the patient will follow up with the health department or animal control and will return to a physician for postexposure prophylaxis, based on the finding in the animal.2

**TRAVEL OUTSIDE THE UNITED STATES**

Tens of thousands of people die of rabies worldwide, most commonly after being bitten by an infected dog. In developing countries of Africa, Asia, and Latin America, rabies is common. Preexposure vaccination is indicated only if the patient will have a high likelihood of contact with animals, will remain for an extended period of time, and will have difficulty obtaining postexposure treatment. Even if preexposure prophylaxis is administered, postexposure treatment is still needed.

The World Health Organization (http://www.who.int/rabies/epidemiology) reports that rabies is present on every continent except Antarctica. Of 145 countries reporting, 45 note no cases of rabies. These rabies-free countries include selected islands such as New Zealand, Japan, Fiji, and Barbados, as well as certain developed European countries such as Greece, Portugal, and Scandinavian countries. In Latin America, Chile and Uruguay are noted to be free of rabies.

If a patient has had an exposure outside the United States, contact the CDC regarding the risk and the need for postexposure prophylaxis. Presume that prophylaxis should be initiated unless convincing evidence is present to the contrary. Initiate prophylaxis even if the wound is healed and the exposure was remote.

If a patient has begun postexposure prophylaxis outside the United States, obtain as much information as possible regarding the treatment before the patient’s return to the United States. Contact the CDC or state or local health department regarding how to continue postexposure prophylaxis in this patient.

Human-to-human transmission of rabies is possible. Documented cases have involved inoculation through saliva by biting or kissing.27 Human-to-human transmission has also occurred from the transplantation of infected organs.28,29 When providing routine health care to a person with rabies, the use of appropriate contact isolation practices prevents rabies exposure in the health care provider.30 No known case of transmission of rabies to a health care worker from a patient exists.2 Treat persons who have been stuck with a contaminated needle from a patient with rabies as a rabies exposure. The concern is that the needle may contain neural tissue.

Incubation periods of up to 6 years have been reported for rabies.17 For this reason, if exposure to rabies may have occurred, start postexposure prophylaxis regardless of the time from the exposure.6 Adhere to the postexposure prophylaxis protocol as with any other exposure (see the “Tips and Tricks: Postexposure Prophylaxis” box).

**WOUND TREATMENT AND RABIES PREVENTION**

Postexposure prophylaxis consists of three steps: wound care, conferring of passive immunity, and active immunization. When World Health Organization guidelines for postexposure prophylaxis are followed, postexposure prophylaxis is effective. Postexposure prophylaxis failures have all involved deviation from the guidelines.2

The first step in rabies postexposure prophylaxis is local wound care. Copiously irrigate the wound with soap and water. Follow with treatment with a virucidal agent, such as povidone-iodine. Wound care alone decreases the chance of contracting rabies.31 Failures of postexposure prophylaxis have been attributed to inadequate local wound care.2

The second step in postexposure prophylaxis is passive immunization. It takes approximatively 7 days to develop an antibody response to rabies vaccine. Rabies immune globulin (RIG) provides passive immunization until the antibody response begins. Administer 20 units/kg of RIG. This dose is the same for pediatric and adult patients. Infiltrate as much RIG as possible into the wound and tissue immediately surrounding the wound. Administer the remaining dose of RIG intramuscularly at a site remote from the vaccination site.

If the patient presents with a bite or wound that is already infected, clean the wound appropriately. Débride and incise the wound as needed. RIG can be infiltrated safely into an infected wound following proper local wound care.6

The third step in postexposure prophylaxis is vaccination (see the “Tips and Tricks: Postexposure Prophylaxis” box). Three cell culture vaccines are available in the United States: human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), and purified chick embryo cell vaccine (PCEC). These vaccines are all equally efficacious, and the dose and administration are the same for all three types.

Administer 1 mL of vaccine intramuscularly. The vaccine is administered intramuscularly into the deltoid muscle of adults. The vaccine can be administered intramuscularly into the deltoid or anterior thigh of a child. Vaccine failures have
been recorded for administration of vaccine into sites other than the deltoid of adults.\textsuperscript{25} Do not administer vaccine into the same intramuscular region as RIG was administered. Do not use the same syringe to administer vaccine and RIG.

The first day of vaccination is day 0. Inform the patient that four additional vaccinations are required, on days 3, 7, 14, and 28. The subsequent doses are the same, 1 mL intramuscularly. Postexposure prophylaxis should not be modified or discontinued unless the animal is found by laboratory testing to be free of rabies. If interruption of the postexposure prophylaxis schedule occurs, contact the local health department or the CDC to determine the new schedule.

Some people have been previously vaccinated against rabies. If they are exposed to rabies, previously vaccinated people undergo a modified vaccination regimen with two doses of vaccine, one dose on day 0 and one dose on day 3 (see the “Tips and Tricks: Postexposure Prophylaxis Vaccination” box). Administer a 1-mL intramuscular dose of vaccine in the deltoid muscle. Instruct the patient to receive another dose of vaccine on day 3. Do not administer RIG to anyone who has been previously immunized. Provide local wound care, as with any exposure.

Because rabies is considered a fatal disease, postexposure prophylaxis is not withheld during pregnancy. Inform pregnant patients that no known fetal anomalies have been linked to rabies postexposure prophylaxis,\textsuperscript{33-35} but extensive testing in humans has not been performed. When possible, discuss the case with the patient’s obstetrician.

Patients who are immunocompromised as a result of chronic illness or immune-modulating drugs require monitoring for immune response. Administer the same dose of vaccine and RIG, and provide appropriate wound care. If possible, discuss the case with the patient’s primary physician or infectious disease specialist. Refer the patient to the patient’s primary physician or infectious disease specialist for the remainder of the vaccination course and the appropriate antibody titers. Monitoring for immune response is outside the scope of emergency medicine.

**TREATMENT**

Rabies is considered a fatal disease.\textsuperscript{5} Only six known cases of survivors of clinical rabies have been reported, and in five of these cases, patients had some form of rabies immunization before the onset of clinical disease. Four of the six survivors had neurologic devastation.\textsuperscript{8-11}

**SYMPTOMATIC RABIES**

Once clinical signs or symptoms of rabies have begun, no reliably successful rabies treatment is known. Treatments are all considered experimental and have included antiviral therapy with ribavirin, vidarabine, and interferon alfa.\textsuperscript{5,36,37} Rabies vaccine has not been demonstrated to have a beneficial effect in animal models when it is administered after the onset of clinical disease. RIG is of unknown benefit in clinical disease, but it is administered.\textsuperscript{5} Ketamine has been used to induce coma and has been shown to decrease viral replication in rat models. This drug is of unknown clinical benefit in humans.\textsuperscript{38} Corticosteroids are associated with increased mortality in laboratory studies. Avoid corticosteroids in patients suspected of having rabies encephalitis.\textsuperscript{5} Because of the lack of an effective therapeutic regimen, the treatment of rabies involves consultation with local or state health departments and the CDC, in conjunction with an infectious disease specialist and intensive care specialist, when available. The responsibility of the EP is to maintain a level of suspicion for rabies in a patient with signs of encephalitis, to consult for definitive diagnosis and management of rabies, and to provide supportive care while the patient is in the emergency department (ED). The determination of an effective antiviral regimen for a patient with suspected or confirmed rabies is outside the scope of practice of emergency medicine.

When rabies is suspected, consult the local or state health department, the CDC, or an infectious disease specialist for emergency treatment guidance. Give RIG, 20 units/kg intramuscularly, if significant delay in consultation is encountered. Provide supportive care to the patient. Spasms are painful, and the patient remains aware through much of the clinical course of the disease. When it is not contraindicated because of other comorbidities, administer ketamine by continuous intravenous infusion to sedate the patient and to alleviate the pain of rabies.\textsuperscript{5} Intubate the patient if the patient has lost protective
Patients who have had an exposure to a healthy pet that is undergoing 10 days of observation should be referred to animal control or to the health department. It is the patient’s responsibility to stay in contact with animal control for information regarding the health of the animal.

Patients who have received the first treatment of postexposure prophylaxis are treated as outpatients. When possible, patients should continue the postexposure prophylaxis with a primary care physician or the health department, to ensure continuity of care. If not possible, the patient can return to the ED for the remainder of the postexposure prophylaxis. Patients with suspected clinical rabies require admission to the intensive care unit.

</table>
Many patients with tick-borne diseases (TBDs) do not recall a tick bite; the history should focus on activities that predispose to tick exposure.

Because some of the TBDs are fatal if untreated, consider these diseases in patients with fever of unknown source, especially in “tick season.”

TBDs most often can be strongly suspected or diagnosed clinically, and treatment should be initiated before definitive laboratory confirmation.

**EPIDEMIOLOGY**

Untreated, tick-borne diseases (TBDs) can be associated with significant morbidity or mortality. Definitive treatments exist for the more serious diseases. TBDs usually can be confidently diagnosed clinically, based on pathognomonic or suggestive physical or laboratory findings that are available in the emergency department. Confirmatory laboratory testing is rarely available in real time and is often unnecessary for initial medical decision making. Therefore, physicians must understand both classic and atypical presentations and must be prepared to treat these illnesses based on clinical suspicion.

Because these illnesses frequently occur in the absence of a known tick bite, physicians must consider TBDs when patients present in the correct epidemiologic context and with a recognizable syndrome. This chapter considers these diseases in syndromic groups (patterns of presentation), rather than individually. Individual TBDs are listed in Table 180.1 (North America) and Table 180.2 (worldwide). Travelers may import the TBDs from one location to another.

Epidemiologic context is a key principle in diagnosing TBDs. As in a criminal investigation, the practitioner must assess the tick’s means, motive, and opportunity to transmit a TBD. The means has to do with tick anatomy—the ability to bite a mammal, usually without the mammal’s knowledge. This factor is crucial because most TBDs require many hours of tick attachment to transmit the infectious agent. The motive has to do with tick physiology; ticks require a blood meal from a host to live and transform to their next life stage. Opportunity relates to patient and geographic factors, that is, epidemiologic context. Taking a history that focuses on this epidemiologic context is essential to the diagnosis of all TBDs. Ask whether the patient has been bitten by a tick, but remember that most patients with TBDs do not recall a tick bite. For example, only approximately 25% of patients with Lyme disease (smaller ticks) and only two thirds of patients with Rocky Mountain spotted fever (RMSF) (larger ticks) recall the bite. Questions directed at whether a tick could have bitten the patient should be asked:

- How do you spend your time?
- What is your job?
- What hobbies and recreational activities do you enjoy?
- Where have you traveled recently?

As for the season, most TBDs are acquired from April through September, but “tick season” depends on the stage of a disease, geography, and local weather patterns for that geographic area. For example, Lyme arthritis could manifest in January from a bite in July, and a warm spell in late fall in North Carolina could result in a case of RMSF that develops in November.

**PATHOPHYSIOLOGY AND TICK ANATOMY**

Two families of ticks are important in human TBDs. Hard (Ixodidae) ticks tend to attach and feed for days, whereas soft ticks (Argasidae) feed in minutes to hours. Table 180.3 lists some characteristics of these different types of ticks. Because the hard ticks, which transmit most of the human TBDs, feed for so long, tick removal during the first 24 hours of attachment provides one strategy for disease prevention, a concept best studied in the context of Lyme disease. Figures 180.1 to 180.3 show various stages of Ixodes scapularis, Dermacentor variabilis, and Amblyomma americanum ticks.

Because multiple TBDs are covered in this chapter, specific pathophysiology for each of the TBDs is covered in the next section.

Fig. 180.1  *Ixodes scapularis* ticks, nymphal stage. Two nymphal *I. scapularis* ticks are shown next to a common household match. The tick on the left has been feeding on a mouse for 48 hours and is larger than the unfed tick on the right. Seen in three dimensions, the fed tick is more spherical, whereas the unfed tick is flatter. (Photograph by Darlyne Murawski.)

Fig. 180.2  *A Dermacentor variabilis* tick next to an *Ixodes scapularis* tick. This photograph shows an adult *D. variabilis* (left) tick next to an adult *I. scapularis* (right) tick, both next to a common match for scale. In cases of Rocky Mountain spotted fever, even with this larger tick vector, 30% to 40% of patients are not aware of a tick bite. (Photograph by Darlyne Murawski.)

Fig. 180.3  *Amblyomma americanum* tick. An adult female Lone Star tick next to a nymph of the same species. This tick is responsible for transmission of human monocytic anaplasmosis and Master disease. (Photograph by Darlyne Murawski.)

Mediterranean spotted fever

Relapsing fever

TBDs most commonly manifest as one of four syndromes (Table 180.4):

- Localized rash (with or without fever)
- Febrile illness without prominent rash
- Febrile illness with diffuse rash
- Acute neurologic illness

Other possible presentations are possible, especially with respect to atypical presentations of any of these diseases and, most notably, Lyme disease. The other signs and symptoms of Lyme disease are discussed separately.

Before discussing the individual syndromes and diseases, the physician should know that as often as 20% of the time, a single tick bite results in multiple infections. Therefore, a patient may develop the rash of Lyme disease along with babesiosis or anaplasmosis. This possibility has implications with respect to the manifestations of the diseases and also the choice of antimicrobials.

**LOCALIZED RASH (WITH OR WITHOUT FEVER)**

A localized rash from TBD occurs in early Lyme disease and ulceroglandular tularemia. Tularemia has multiple presentations, but the ulceroglandular form, which accounts for 80% of cases, usually starts with a papule that evolves into an ulcer on an extremity at the site of a tick bite (or animal exposure). The lesion evolves into a necrotic eschar and is often associated with regional lymphadenopathy, fever, and other systemic signs.

Mediterranean spotted fever and some of the African spotted fevers also manifest with a local eschar at the site of a tick bite, sometimes called a “tache noire.”

Erythema migrans (EM), the rash of early localized Lyme disease, is an important condition that emergency physicians should be familiar with because antibiotic treatment at this stage almost always leads to excellent outcomes. Lyme disease is by far the most common vector-borne illness in North America.
EM attains this size without fever, significant tenderness, and other systemic findings. Some patients with EM have fever, headache, myalgias, neck pain or stiffness, and other systemic symptoms. The fever is usually low grade, and high fevers suggest coinfecting babesiosis or anaplasmosis. Roughly 10% to 20% of patients with early Lyme disease have multiple cutaneous lesions (see later).

Although EM has always been thought to be pathognomonic of Lyme disease, EM-like lesions have been reported in the southeastern and central states; this has been called Master disease or southern tick-associated rash illness (STARI). Although these patients' rashes have some differences from classic EM in patients from Lyme-endemic states, significant overlap can occur in individual patients. Other novel Borrelia species may cause this lesion, and these patients should also be treated with antibiotics, similar to patients with Lyme disease.

FEBRILE ILLNESS WITHOUT PROMINENT RASH
Most TBDs can manifest as a nonspecific febrile illness. These diseases are babesiosis, anaplasmosis, tularemia, Colorado tick fever, relapsing fever, and Q fever. Lyme disease can also manifest this way, although the frequency of this presentation is unclear. Typical patients with RMSF do not have a rash until the third to the sixth day of illness, and in as many as 15% of patients, a rash never appears. If RMSF is a real diagnostic possibility on epidemiologic grounds, treat with empiric antibiotics even in the absence of a rash. Finally, all these diseases that typically present without rash are sometimes associated with nonspecific, usually maculopapular rashes.

Anaplasmosis (formerly called ehrlichiosis), a relatively newly described illness, has a presentation similar to that of

---

**Fig. 180.4 Classic erythema migrans.** Note the location (torso) and the bull’s-eye appearance in this patient with fever and localized rash, which was flat and neither painful nor pruritic. A suggestion of a central punctum, the location of the tick bite, is evident.

**Fig. 180.5 Erythema migrans with a raised, vesicular center.** This patient presented in early July after having pulled a tick off himself 7 days earlier. Approximately 18 hours after starting doxycycline, the patient had a Jarisch-Herxheimer reaction (abrupt onset of chills, tachycardia, intensification of rash), which occurs with treatment of spirochetal diseases.

**Fig. 180.6 Erythema migrans with a homogeneous color.** This young man had a rash that had been ascribed to a spider bite but was growing larger. The rash was painless, thus making a spider bite much less likely. The patient also had a tender, palpable lymph node in the right axilla.
RMSF but without the rash. The two most common forms in humans are granulocytic and monocytic (terms based on the tropism of the organisms toward white blood cells). These patients complain of high fever, headache, and myalgias. The spectrum of disease is wide, and published series likely emphasize sicker patients. As in RMSF, some patients have prominent encephalitis, noncardiogenic pulmonary edema, and shock.

Babesiosis, a malaria-like parasitic infection transmitted by *I. scapularis*, is diagnosed with increasing frequency in areas of the United States where this tick is active. The usual agent in North America is *Babesia microti*. Infection results in a wide spectrum of illness ranging from asymptomatic seroconversion to mild flulike illness, to malaria-like illness, or even overwhelming sepsis and death. Fever, fatigue, headache, sweats, and chills are the most common symptoms. Hepatosplenomegaly may be present. Complications include hemolysis and renal failure, noncardiogenic pulmonary edema, and coma. Patients with babesiosis can be ill for weeks to months and may have subacute or chronic illness. Splenectomized patients have an unusually fulminating course.

Colorado tick fever is a viral illness that occurs in the Rocky Mountain states and southwestern Canada and is transmitted by *Dermacentor andersoni* at elevations of 1200 to 3300 m. Only a few hundred cases are diagnosed annually in the United States. The presentation is nonspecific (fever, headache, and myalgias), but the fever often follows a characteristic “saddle-back” pattern (two periods of 2 to 3 days of fever, punctuated by an afebrile interval). Occasionally, a small, red, painless papule is seen, and less commonly, patients have a nonspecific generalized rash. Pharyngitis, lower gastrointestinal symptoms, and central nervous system (CNS) symptoms may also occur in some cases.

Q fever manifests as a nonspecific febrile illness sometimes associated with hepatitis or pneumonia. Hepatitis is particularly common. Other organ systems, especially the heart and CNS, may be affected, and a few patients also exhibit a nonspecific maculopapular rash. Q fever may become chronic, and in these patients, it often affects the heart (endocarditis), blood vessels, and liver. The diagnosis is established by serologic methods and by polymerase chain reaction because the organism is very rarely cultured.

Typhoidal tularemia manifests as a nonspecific febrile illness and headache and is uncommon. Tularemic pneumonia may develop. One outbreak of this form of the disease that occurred on Martha’s Vineyard (an island off the coast of Massachusetts) likely resulted from inhalation of ticks aerosolized by power lawn mowers.

Relapsing fever is caused by various *Borrelia* species transmitted by *Ornithodoros* species, soft ticks that feed for very short times. This illness is characterized by intervals of fever interspersed with afebrile periods. The explanation of these episodes is that the *Borrelia* organisms undergo antigenic shifting, thus presenting a new antigen to the patient’s immune system. After an incubation period of approximately 1 week, patients develop fever, headache, myalgias, and chills. Abdominal pain and altered mental status are common. Untreated, most patients improve and then suffer a relapse from the new antigenic variety 1 week later. Complications include focal neurologic findings (including seventh nerve palsy), myocarditis, and ruptured spleen.

**FEBRILE ILLNESS WITH GENERALIZED RASH**

Many TBDs can manifest with fevers in which a generalized rash is a prominent manifestation of the illness. RMSF is the most dramatic of these illnesses; patients present with fever, headache, myalgias, and rash. The classic triad of fever, headache, and rash in a patient with a recent tick bite is seen in a few patients. Even with the larger tick vector, only approximately two thirds of patients recall the tick bite. In addition, the rash of RMSF does not develop until the third to the sixth day of the illness. The rash begins as a maculopapular rash that becomes petechial and finally may evolve into frank ecchymosis. The classic description of a rash that begins acrally and spreads centrally does not always apply. Thus, the rash can vary from nonexistent to frank skin necrosis. Because the organisms cause small vessel vasculitis, the manifestations are based on the particular organs affected. Patients can present with a surgical abdomen, an illness resembling meningitis, myocarditis, renal failure, or circulatory collapse. Untreated, RMSF has a mortality rate of 25% to 40%. Therefore, considering this diagnosis in any febrile patient with the correct epidemiologic context is important, because early antibiotic treatment reduces the mortality rate to less than 5%.

Early disseminated Lyme disease with secondary EM is the other TBD that manifests as fever and generalized rash. Secondary lesions occur approximately 20% of the time and imply hematogenous spread of the organism. The secondary lesions differ from the primary EM lesion in that they tend to be smaller, lack the central punctum, and exhibit less central clearing.

**ACUTE WEAKNESS**

The one TBD that is not caused by an infectious agent is tick paralysis. This illness can be caused by several tick species that produce neurotoxins. Patients present with gait instability, acute ascending weakness, and sometimes cranial nerve findings that suggest Guillain-Barré syndrome. Children, often girls with long hair, are more frequently affected, and the scalp of these patients must be very carefully inspected. The diagnosis is established by finding an engorged tick, the removal of which is also the treatment of this rare disease.

Despite (or perhaps because of) the rarity of this disorder, consider this entity in all patients with acute onset of weakness. Cases have been reported in the Philadelphia area (acquired locally) and in Los Angeles (likely contracted in Montana). The neurologic findings resolve over 6 to 24 hours. Finding the tick precludes the need for more expensive and invasive evaluation and prevents deaths. Patients have no fever and no alteration of consciousness.

Lyme disease can also manifest with different kinds of focal weakness resulting from meningealilitis; the deficit depends on which nerve roots are involved. Of course, any febrile illness can lead to overall nonlocalizing malaise.

**OTHER MANIFESTATIONS OF LYME DISEASE**

Lyme disease has been traditionally divided into three phases (Table 180.5). Early localized disease is characterized by EM, although some authors include flulike illness in this stage. Early disseminated disease typically involves the skin, heart, joints, and nervous system. Late disseminated disease generally affects the joints, nervous system, and (in Europe) the skin. Although early disseminated Lyme disease has many
potential manifestations, the common and important manifestations for emergency physicians are cranial nerve palsy, meningitis, carditis, and arthritis.

Any cranial nerve can be affected, but seventh nerve palsy is by far the most common. Bilateral facial involvement is not uncommon in patients with Lyme-induced facial palsy. Controversy exists regarding the appropriateness of lumbar puncture in these patients. The major question is this: Should the presence of pleocytosis mandate parenteral therapy or not? Although this question has no definitive answer, many physicians favor lumbar puncture and treat the patient parenterally if the cerebrospinal fluid shows abnormalities. A European study suggested that this approach is not necessary. Lyme meningitis, which can occur with or without other neurologic abnormalities, can be surprisingly “quiet” with respect to symptoms. Headache may be mild and intermittent, and meningeal signs are often absent.

Carditis occurs in 5% to 10% of untreated patients, usually in young male patients. It has a predilection for the conduction system and often leads to complete heart block. Although temporary cardiac pacing is indicated, permanent pacemakers are rarely necessary. Arthritis is usually a late finding, but it can also occur in the early disseminated phase.

### Differential Diagnosis and Medical Decision Making

The differential diagnosis in these patients depends on the specific presenting syndrome and is largely covered in the previous section. A complete differential diagnosis of EM includes various other acute rashes. Physicians should diagnose early localized Lyme disease and tick paralysis by history and physical examination. Fifty percent of patients with EM have a negative Lyme serologic test result; therefore, no testing is necessary because a negative result should not dissuade the physician from diagnosing EM and treating it. Serologic testing is not indicated in most patients with EM.

The differential diagnosis of undifferentiated fever is enormous and includes just about every cause of fever. In patients with fever and generalized rash, one must consider bacteremia and viremia, especially meningococcal and streptococcal and staphylococcal sepsis. Physicians should also treat suspected RMSF empirically without waiting for diagnostic test confirmation. Table 180.6 gives clues to the diagnosis of TBDs.
Physicians can often confidently diagnose babesiosis (Fig. 180.7), anaplasmosis (Fig. 180.8), and relapsing fever (Fig. 180.9) on the basis of a blood smear. Although numerous antigen and antibody tests are available for all these diseases, the results of these tests are hardly ever available in real time.

For later manifestation of Lyme disease, the Centers for Disease Control and Prevention currently recommend a two-step testing procedure (screening enzyme-linked immunosorbent assay followed by a confirmatory Western blot). Newer tests, especially the C-6 peptide, hold promise for a single-tier test. In these patients, the physician must carefully interpret the serologic results in the context of the patient’s symptoms, clinical course, and epidemiologic features.

In patients with acute weakness, tick paralysis can be confused with Guillain-Barré syndrome, myasthenia gravis, botulism, hypokalemic paralysis, organophosphate poisoning, transverse myelitis, and spinal cord compression.

**Fig. 180.7** Blood smear showing babesiosis. This figure shows intraerythrocytic ring forms in multiple red blood cells from a patient with a high parasite count.

**Fig. 180.8** Blood smear showing a morula in a patient with anaplasmosis. This blood smear shows two morulae (intracellular clumps of anaplasma organisms in the white blood cell to the right) that can be diagnostic in a patient with anaplasmosis. (Courtesy of Dr. J. S. Dumler.)

**Fig. 180.9** Blood smear showing relapsing fever *Borrelia*. This blood smear shows a spirochete in the blood from a patient with relapsing fever.

### TIPS AND TRICKS

- Most patients with Lyme disease and approximately one third of patients with Rocky Mountain spotted fever (for which the tick vector is much larger) do not have a history of a known tick bite.
- Treat patients with presumed Rocky Mountain spotted fever with a tetracycline even if a rash is not yet present.
- Remember that up to 20% of patients with tick-borne disease have more than one infection transmitted by the same tick bite.
- Examine the whole body, and particularly the scalp, in all patients presenting with acute significant weakness or a clinical picture resembling Guillain-Barré syndrome. This is especially important in young children and occurs most often in young girls.
- In early localized Lyme disease with erythema migrans, serologic testing is not indicated or helpful, unless the clinical findings and situation are very atypical or ambiguous. Serologic test results are normal approximately 50% of the time.
- In children, even those younger than 9 years of age, with life-threatening cases of Rocky Mountain spotted fever or anaplasmosis, use intravenous doxycycline initially.

### TREATMENT

Tick removal is best accomplished by using fine forceps applied close to the skin and gradually pulling the tick upward and outward. Because ticks use a cement-like substance to embed, this removal procedure may take steady gentle pressure over a minute or two. Try to remove the entire tick. Retained mouth parts may cause a foreign body reaction or a staphylococcal or streptococcal skin infection, but they have no implications in terms of TBD transmission.

No specific antimicrobial therapy exists for Colorado tick fever or tick-borne encephalitis. The definitive treatment for tick paralysis is tick removal; improvement often begins within hours.

ICU, Intensive care unit; IV, intravenous.
*The choices of antibiotics, route, dose, and duration should be made on a case-by-case basis, depending on the severity of illness, allergies, age of patient, pregnancy, and other individual factors.

Table 180.5 shows the treatments for specific manifestations of Lyme disease. Treat patients with the remaining bacterial TBDs with specific antimicrobial therapy (Table 180.7). Data suggest a trend toward shorter courses of antibiotics in patients with early Lyme disease.5,6

The threshold to treat should be low, and frequently the decision to treat is based purely on presentation and epidemiologic context. Although tetracyclines are generally contraindicated in children less than 9 years of age, short courses of intravenous doxycycline are indicated in children with life-threatening manifestations of RMSF or anaplasmosis.

FOLLOW-UP, NEXT STEPS, AND PATIENT EDUCATION

Most patients with TBDs can be treated as outpatients with primary care follow-up. Patients with syndromes requiring intravenous antibiotics, cardiac pacing, or intensive care for CNS, respiratory, renal, or circulatory failure should be admitted to an appropriate inpatient setting. Consultation with specialists is on a case-by-case basis.

PATIENT TEACHING TIPS

If you cannot avoid tick exposure, do daily tick checks, and carefully remove any ticks found.

If you become ill and have either been bitten by a tick or been exposed to ticks, be sure to mention this to your doctor, even if you develop new symptoms weeks or months later. The tick bite could possibly cause delayed problems.

181 Tuberculosis

D. Matthew Sullivan

**PATHOPHYSIOLOGY**

*Mycobacterium tuberculosis* is a small, slow-growing bacterium that is transmitted by inhalation of droplet nuclei. As infected persons talk, cough, or sneeze, numerous nuclei are expelled into the surrounding air. Only a few inhaled droplets are needed to infect, so an increased length of exposure to the pathogen and the number of bacilli present correlate with infectivity.1

Inhaled bacilli travel down the bronchi and lodge within an alveolus. Activated macrophages then ingest the bacilli, which replicate and ultimately cause lysis. Monocytes are attracted and differentiate into macrophages, which again consume the mycobacteria and form a tubercle. The tubercle travels through the lymphatic and hematogenous systems and lodges in the lung apices, lymph nodes, meninges, vertebra, long bones, or kidney.

Two to 3 weeks after infection, cell-mediated immunity converts the tubercle to a granuloma by means of CD4 helper T cells. This process arrests the local infection for most immunocompetent hosts. At that time, the only sign of the disease may be a positive reaction to the purified protein derivative (PPD) skin test.

A delayed hypersensitivity response uses cytotoxic killer CD8 suppressor T cells to kill the other nonactivated macrophages with bacilli. This process creates local tissue destruction and the formation of a caseating granuloma. In immunocompromised patients, this caseous center may expand and then calcify to form a Ghon complex in the lung. If the infection is uncontrolled, primary tuberculous pneumonia may ensue, or infection may spread through blood and lymph, with resulting disseminated TB.2

Active TB develops months to years later in those patients with decreased capacity for cell-mediated immunity, such as patients with malnutrition, comorbidities, and immunosuppression. Patients with acquired immunodeficiency syndrome are especially prone to develop active disease. As the caseating granuloma liquefies and releases numerous bacilli, a delayed hypersensitivity response is initiated, and local tissue destruction follows. Ultimately, erosion through a bronchial wall creates a cavitary lesion and the development of pneumonia. The high oxygen tension of the cavity lends itself to replication of bacilli and persistent disease.

**KEY POINTS**

- Despite advances in diagnosis and therapy, tuberculosis (TB) remains a leading cause of death worldwide.
- TB begins as a primary infection (usually in the lung, but other organ systems may be involved) that enters a latent period.
- Immunocompromised patients are at increased risk of reactivation of the disease and the development of active TB.
- The presentation of TB can be very broad and should remain in the differential diagnosis in all patients who present with systemic signs of infection.
- Therapy for TB should include multiple drugs to which the mycobacterium is susceptible and should continue for at least 6 to 12 months.
- Because of the risk of multidrug-resistant TB, an initial four-drug regimen with isoniazid, rifampin, ethambutol, and pyrazinamide is recommended.

**CLASSIC PRESENTATION**

The symptom constellation of cough, night sweats, and hemoptysis, commonly associated with TB, is of little benefit in the early identification of disease because TB often has no early symptoms. Late symptoms are wide ranging and do not always involve the respiratory tract. Extrapulmonary manifestations of TB are seen in 20% of patients when the host is immunocompetent and are even more common when the host is immunocompromised.3 In patients with one or more risk factors for TB (Table 181.1 and Box 181.1), a detailed history helps to refine the pretest probability for the diagnosis of TB.

Early stages of infection are most often asymptomatic in the normal host. Unless cell-mediated immunity is impaired, symptoms may manifest only after reactivation of the infection. Patients may present with a combination of systemic symptoms including cough, fatigue, fever, anorexia, malaise, and weight loss. An indolent cough that has progressed over more than 2 weeks should raise the clinical suspicion of pulmonary TB.5 Hemoptysis signifies erosion into the bronchial

Box 181.1 Populations at Risk for Contracting Tuberculosis

Persons with human immunodeficiency infection
Persons with exposure to a known case
Persons of Asian, African, or Latin American descent
Migrant farmers
Homeless persons
Persons of low income
Older persons
Nursing home residents
Correctional facility residents
Intravenous drug users
Persons with occupational exposure

tree and is unlikely to be an early symptom of pulmonary TB. When the clinical suspicion is raised, the physical findings in pulmonary TB may include fever, pleural effusion, focal pneumonic auscultatory findings, and adenopathy.

Variations

Extrapulmonary manifestations clinically conform to the site of infection, and care should be taken to include TB in the differential diagnosis in patients who present with the following conditions:

- Diffuse adenopathy of the neck (scrofula)
- Recurrent urinary tract infections, scrotal mass, prostatitis, epididymitis, or orchitis (genitourinary TB)
- Headache, fever, meningeal signs, or altered mental status (TB meningitis)
- Focal neurologic deficits, cranial nerve abnormalities, cerebellar dysfunction, or seizure (central nervous system tuberculomas)
- Joint or spinal pain (Pott disease)
- Chest pain or dullness to percussion (pleural TB)
- Multiple organ system disease (disseminated TB)

Differential Diagnosis

Depending on the clinical symptoms at presentation, TB may mimic numerous systemic diseases. Radiographic findings, sputum smears, and skin tests help in the diagnosis of TB. The “gold standard” diagnostic test is culture, and results may not be available for several weeks (Table 181.2).
**RED FLAGS**

- Failure to consider extrapulmonary tuberculosis in the differential diagnosis
- Tuberculosis in immunocompromised patients or those at the extremes of age
- Tuberculosis in patients with risk factors for multidrug-resistant tuberculosis
- Patients with social concerns who may not be able to fulfill directly observed therapy

**DIAGNOSTIC TESTING**

Latent TB in asymptomatic patients is clinically difficult to identify. Targeted population screening has been advocated as a means to identify early disease while it is still in the more easily treated latent period. Current recommendations are to perform a PPD skin test on patients who would benefit from therapy for latent TB and who are at high risk of developing active TB (Box 181.2). Currently, the foundation of screening is skin testing with PPD in patients at risk for TB. Patients who harbor latent TB and who have intact cellular immunity demonstrate a hypersensitivity reaction at the site of PPD placement that can be graded and evaluated with a well-established scale reflecting positivity or negativity (Table 181.3). This type of screening is not particularly sensitive in immunocompromised patients, older patients, newly infected patients, or very young children. Additionally, the PPD test lacks the specificity to distinguish among other Mycobacterium infections. Newer whole-blood antigen-stimulated interferon-γ release assays are available that have high sensitivity and specificity, are not affected by prior bacille Calmette-Guérin vaccination, and do not have a waning response over time. As genomic testing becomes more widely available, the ability to predict disease progression based on the genetic expression of an individual patient may play an important role in diagnosis.

The advent of auscultation and radiography greatly advanced the diagnosis of TB in the eighteenth and nineteenth centuries. Despite technical advances in diagnostic tests, history, physical examination, and conventional radiography remain cornerstones in the diagnosis of TB in the emergency department (ED). Frequently, patients who present to the ED with symptoms of pulmonary or extrapulmonary TB have limited prior access to care, and heightened suspicion is required. Once a history is obtained that suggests active pulmonary disease, patients should be isolated (in a negative-pressure room, if possible), and a chest radiograph should be obtained. The identification of an upper lobe infiltrate suggests the presence of active disease (Figs. 181.1 and 181.2). Chest radiography is not highly sensitive, particularly in the immunocompromised patient, in whom reticulonodular and miliary patterns of disease may be present. The clinical syndrome of normal chest radiographs with sputum culture-positive TB is well described in patients with human immunodeficiency virus (HIV) infection and low CD4 counts. In these patient populations, a high clinical suspicion for disease mandates that sputum studies be ordered.

Unfortunately, sputum Gram stain with carbol-fuchsin and phenol or auramine O staining for the identification of acid-fast bacilli (AFB) is unreliable in the ED evaluation of patients suspected to have TB. In addition to the variability in performance inherently linked to the skill of the laboratory technical staff, and the availability of rapid test results at all times of day, the sensitivity of a single AFB smear remains low (<50%), far too low for the safe discharge of the high-risk patient. This situation necessitates further management by the inpatient team or close follow-up with the local health department for further sputum smears in those patients who are deemed safe for discharge. The additive value of three morning sputum smears is helpful for excluding the diagnosis of active pulmonary TB. When AFB smears are identified, distinguishing among Mycobacterium species is not possible, and the definitive diagnosis should be confirmed with sputum culture.

Sputum culture is not part of the ED evaluation of a patient with suspected TB. Cultures traditionally take 4 to 8 weeks to grow. Cultures are sensitive in more than 80% of cases of infiltrative pulmonary TB and in more than 90% of cases of cavitary TB. Newer methods of radiometric culture systems with radiolabeled carbon-14 yield faster results (1 to 3 weeks).

The advent of nucleic acid amplification tests and of polymerase chain reaction identification greatly increased the sensitivity (97% to 99%) for the diagnosis of TB from a single sample, and accurate results can be obtained in hours. Additional strain typing for M. tuberculosis with restriction fragment length polymorphism is available to identify the organism’s DNA. Even for large centers, these tests are time and resource consuming to perform on an as-needed basis, and they are impractical for use in the ED work-up of patients.

**BOX 181.2 Indications for a Purified Protein Derivative Skin Test**

- Increased risk of exposure to infectious cases
- Close contacts of persons with known active TB
- Health care workers where TB is treated
- Increased risk of TB infection
- Foreign-born persons from a country with a high prevalence of TB
- Homeless persons
- Persons living or working in long-term care facilities
- Increased risk of active TB once infection has occurred
- Persons infected with human immunodeficiency virus
- Intravenous drug users
- Persons receiving immunosuppressive therapy
- Patients with end-stage renal disease
- Patients with silicosis
- Diabetic patients
- Patients with hematologic malignant diseases
- Patients with prior gastrectomies
- Patients with prior jejunoileal bypass
- Persons with severe malnutrition
- Persons with recent TB infection

with suspected TB. The utility of these newer tests in smear-negative individuals has been called into question with reports of lower sensitivities (70%) in this population.15

Extrapulmonary TB is often confirmed by biopsy of affected tissues and lymph nodes. Blood culture, urine culture, and culture of other body fluids are used to aid in the diagnosis of extrapulmonary TB, with varying sensitivities, depending on the host and the site of culture. The diagnosis of pleural TB is facilitated with pleural biopsy and culture; yields are 86% in immunocompetent patients and 47% in immunocompromised patients.15

Ultimately, the diagnosis of TB remains firmly grounded in the clinician’s analysis. A high suspicion of disease, coupled with appropriate testing for the given presentation, will translate into clinical success (Fig. 181.3).17

**PROCEDURES**

Historically, bleeding, leeches, cupping, application of animal excrement, “touching” by kings, pleurocentesis, and the isolation of patients in sanatoriums were used to treat TB. More modern medical times have seen the use of surgical pneumonectomy, thoracoplasty, pneumothorax, and phrenic nerve interruption as potential therapeutic procedures.9 The only procedure infrequently used today is surgical resection.
Inhibition

**PULMONARY TUBERCULOSIS**

Prevention of the spread of TB is paramount in the treatment regimen, and involvement of the local health department ensures a higher success rate. Empirically in the ED, start patients with suspected TB on a drug regimen after obtaining sputum for AFB smears and cultures.

Treatment consists of two phases: the initiation (bactericidal) phase, lasting 2 months; and the continuation (sterilizing) phase, usually lasting 4 to 7 months. Because of the risk of multidrug-resistant organisms, at least two drugs should be used. The American Thoracic Society, the Centers for Disease Control and Prevention, and the Infectious Diseases Society of America recommend an initial four-drug cocktail of isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (ETH) for 2 months (Table 181.4). Directly observed therapy increases completion rates for pulmonary TB and prevents the spread of disease.18-20

Immunocompetent patients become noninfectious 2 to 4 weeks after initiating therapy if the organism is susceptible. If the initial treatment regimen fails, then at least two additional drugs should be added.20 Usually, PZA or another

first-line agent is coupled with a second-line agent such as ethionamide or a fluoroquinolone.\

**Special Populations**

**PATIENTS INFECTED WITH HUMAN IMMUNODEFICIENCY VIRUS** Because of specific drug interactions and resistance, HIV-infected patients present a challenge to standard treatment protocols. Many of the anti-TB drugs have overlapping toxicities with the antiretroviral agents, and some anti-TB drugs may decrease the concentration of certain antiretroviral agents as a result of cytochrome system interactions. HIV-infected patients should not receive once-weekly INH-RIF combinations because of high relapse rates. Patients with CD4 counts lower than 100 cells/mL should receive the anti-TB regimen at least three times a week because of the potential for RIF resistance. If sputum cultures are still positive at 2 months, the continuation phase of treatment may need to be extended to 7 months. Coordination with the infectious disease specialist during treatment of these patients is important.

**MULTIDRUG-RESISTANT ORGANISMS** By definition, *multidrug-resistant TB* is disease that is resistant to two or more first-line agents, usually INH and RIF. Multidrug-resistant TB results from improper treatment regimens, noncompliance with therapy, and spontaneous mutations of the mycobacterium (Box 181.3). These patients should be treated with alternative drug regimens that include at least three drugs to which the organism is susceptible and that have not been previously administered. Ideally, one of these drugs should be injectable.

**PREGNANCY** Pregnant patients may be treated with INH, RIF, and ETH. These drugs do cross the placenta, but they are not known to have any teratogenic effects. Adjuvant pyridoxine should be given to decrease the potential for the development of peripheral neuropathy.

**CHILDREN** Disseminated TB occurs more frequently in children, so treatment of initial infection should be aggressive. Children may be treated with the same drug regimen as adults, with the exclusion of ETH. A regimen of 2 months of RIF, INH, and PZA, followed by 4 months of RIF and INH, has a treatment success of 95%. Children must have directly observed therapy. Children with disseminated TB, TB meningitis, and HIV infection may need an extended treatment period of 9 to 12 months.

**EXTRAPULMONARY TUBERCULOSIS**

Most patients with extrapulmonary TB infections may be treated with the same drug regimen as patients with pulmonary TB. In patients with TB pericarditis or meningitis, corticosteroids are added to prevent pericardial constriction and neurologic sequelae, respectively. A regimen of 6 to 9 months of treatment is adequate for most infections, but patients with meningeval infection require 9 to 12 months of therapy.

**LATENT TUBERCULOSIS**

Patients with latent TB who are at high risk of developing active TB need empiric therapy. Before INH is initiated, patients require a chest radiograph and clinical evaluation to exclude active TB. The preferred treatment regimen for latent TB is daily INH for 9 months.

**MYCOBACTERIUM BOVIS BACILLE CALMETTE-GUÉRIN VACCINE**

Bacille Calmette-Guérin is an attenuated strain of *Mycobacterium bovis* that is the only current vaccine for TB. It was developed by Albert Calmette and Camille Guérin in the early twentieth century and remains the most commonly used vaccine in the world. Unfortunately, its efficacy may be waning as a result of mutations and deletions in the bacterium. Interest in creating alternative improved vaccines has been renewed.

**DISPOSITION**

Most patients with TB may be treated as outpatients as long as directly observed therapy can be ensured, usually by the health department. Admit patients with significant comorbidities, severe disease, a need for parenteral therapy, HIV infection, multidrug-resistant TB, and social situations that would render outpatient therapy unsuccessful.

REFERENCES

Biologic agents have the potential to cause as many casualties in a densely populated area as a nuclear weapon. If used in a terrorist attack on civilian populations, biologic weapons could also result in widespread social disruption and complete exhaustion of health care resources.\(^1\)\(^,\)\(^5\)\(^,\)\(^7\)

The Centers for Disease Control and Prevention (CDC) classified the major bioterrorist threats into three categories, based on the overall danger to the American public.\(^5\) Category A agents are the most easily weaponized and disseminated, cause the highest mortality, produce extensive social disruption, and require special public health preparedness systems. Category B agents do not cause as high mortality as category A agents, but they still result in considerable morbidity and require enhancement of current surveillance systems. Category C agents are the third-highest priority and comprise new and emerging agents that are concerning because of their potential to cause significant morbidity. The list of category A, B, and C agents is given in Table 182.1.

Bioterrorism agents are most dangerous to humans when these agents are in aerosolized form.\(^9\) Particles smaller than 10 mcg effectively reach the alveoli. Certain agents (e.g., anthrax, botulinum) are more resistant to environmental degradation than others (e.g., plague). Some agents (e.g., plague, smallpox) may be transmitted from person to person, thus causing high rates of dissemination and requiring strict isolation measures. Until biologic contaminants are excluded, pulmonary isolation measures should be instituted in all these patients. At present, only anthrax and smallpox have vaccines licensed by the U.S. Food and Drug Administration, and both vaccines require complex administration schedules.\(^9\)

Surveillance and management protocols should be instituted at the hospital level for dealing with large numbers of patients who present with respiratory complaints over a short period of time. If surveillance methods do indicate a bioterrorist attack, the community must work to prevent widespread contamination, to help curb the strain on health care resources. A joint report by the CDC and the U.S. Department of Health and Human Services in February 2007 established guidelines to limit the spread of a pandemic infection.\(^10\) Measures such as the recommendation that ill individuals stay home from work or school, cancellation of large public gatherings, and the use of strict hygiene techniques in the workplace could help avert a health care crisis.

**ANTHRAX**\(^1\)

Anthrax is caused by *Bacillus anthracis*, a gram-positive, aerobic, spore-forming bacillus. It is considered to be the biologic agent most likely to be used in a terrorist attack. A bioterrorist attack with powder containing anthrax spores in the United States in 2001 resulted in 22 confirmed cases. The biologic agent most likely to be used in a terrorist attack. A bioterrorist attack with powder containing anthrax spores in the United States in 2001 resulted in 22 confirmed cases. The bacteria are simple to obtain and grow. The resulting spores can be aerosolized, are extremely resistant to environmental degradation, and can cause untreated mortality rates up to 50% in exposed individuals. A 1970 World Health Organization study estimated that 50 kg of anthrax spores released in a city with half a million people could cause almost 100,000 deaths.

Anthrax causes cutaneous, gastrointestinal, and pulmonary disease. Human infection, usually cutaneous, typically occurs naturally from exposure to domesticated farm animals, such as sheep and cattle. Cutaneous anthrax is responsible for more than 90% of naturally occurring infections. It initially manifests as an erythematous patch, followed by degeneration into necrotic cellulitis with black eschar similar to a brown recluse spider bite. Gastrointestinal anthrax is extremely rare and causes hemorrhagic gastroenteritis and systemic toxicity.

Inhaled anthrax, the bioterrorist threat, causes the highest mortality of all the forms of anthrax. The clinical syndrome is divided into three phases, none exhibiting findings that would allow a clinician to identify the disease definitively. The first phase mimics a nonspecific viral syndrome and is followed by the second phase, which is a 2-day recovery period. The third phase resembles severe bacterial pneumonia, with sudden onset of fever, chills, cough, dyspnea, and respiratory failure. Hematogenous spread can cause meningitis and

necrotizing enteritis. Results of common laboratory tests may be abnormal, but all these tests lack sufficient sensitivity and specificity. Chest radiographs characteristically show mediastinal widening consistent with hemorrhagic mediastinitis. Computed tomography has better sensitivity for mediastinal lymphadenopathy and should be performed in suspected cases when radiographs are normal.

The findings are not sufficiently distinctive from those of other bacterial illnesses to ensure early clinical identification. An astute clinician, noting mediastinal widening on radiographs, should send blood cultures, initiate presumptive antibiotics, and maintain vigilance. Blood cultures and enzyme-linked immunosorbent assay for antibodies to *B. anthracis* are extremely sensitive. Ciprofloxacin is the first-line agent for treatment and postexposure prophylaxis, but doxycycline or amoxicillin may also be used. Decontamination of spores must be accomplished with bleach solution because alcohol does not adequately kill anthrax. Novel immunotherapies involving antibodies to anthrax toxin components are currently under development.

Variola major virus, a double-stranded DNA virus in the Poxviridae family, causes smallpox. The last confirmed, naturally occurring case of smallpox occurred in 1977. Since then, the

**RED FLAGS**

Most cases caused by bioterrorism agents manifest initially as nonspecific viral syndromes.

Inhalational anthrax and pneumatic plague are extremely difficult to distinguish clinically and radiographically, and Gram stain may be necessary.

Cutaneous anthrax is often mistaken for a brown recluse spider bite.

Consider smallpox if large numbers of patients who have already had chickenpox present with a diffuse vesicular rash.

Botulism may resemble organophosphate toxicity or a variant of Guillain-Barré syndrome.

existence of variola major virus has been restricted to laboratories in the United States and the former Soviet Union. Because of the extreme contagiousness of the virus, lack of adequate antiviral therapy, and dissolution of the vaccination program, smallpox has extremely high potential to cause considerable morbidity and mortality as a bioterrorism agent. Mortality rates approach 30% in nonimmunized victims.

Classic smallpox infection initially manifests as a nonspecific viral syndrome 2 weeks after exposure, followed by ulcerated lesions in the oropharynx and face. The characteristic vesicular lesions then develop diffusely over the next few days, which when patients are the most contagious. The vesicles eventually transform into pustules and then crust over in the course of 2 weeks. Chickenpox lesions from varicella-zoster virus may be confused with smallpox lesions. Smallpox lesions are characteristically concentrated on the face and extremities (more than the trunk), are in the same stage of development, and usually follow a virid prodrone lasting several days.

Two uncommon variants of smallpox are important to consider because of their high mortality rates. Flat-type smallpox causes soft, macular skin lesions and multiorgan dysfunction, and it has a mortality rate of 95%. Hemorrhagic-type smallpox results in a hyperacute, diffuse bleeding diathesis and is always fatal.

The treatment of smallpox is purely supportive. Postexposure prophylaxis consists of vaccination, which is effective only if it is administered within 4 days of exposure. Vaccinia immunoglobulin may provide some benefit after smallpox exposure and may reduce dermatologic complications after smallpox vaccination. Strict isolation precautions are indicated, including respiratory isolation for confirmed cases and quarantine of exposed individuals.

PLAGUE

Plague, the infamous “Black Death” of the Middle Ages, is caused by *Yersinia pestis*, a gram-negative, facultative anaerobic coccobacillus. Fleas are the main vector, and rodents are the main reservoir. Bubonic plague, an acute febrile form of lymphadenitis, and septicemic plague still occur naturally in parts of Africa, Asia, and the southwestern United States.

A bioterrorist attack from aerosolized droplets would likely cause pneumonic plague, which is highly contagious and impossible to distinguish clinically from severe community-acquired pneumonia. Hemoptysis is more commonly seen in pneumonic plague than in inhalational anthrax. Buboes, the necrotic lymph nodes characteristic of bubonic plague, are notably absent in pneumonic plague.

No findings on complete blood count, chemistry studies, or imaging tests are sufficiently specific for the diagnosis. Chest radiographs are usually abnormal, exhibiting either alveolar infiltrates or pleural effusions. Blood cultures are positive in 90% of cases, and gram-negative coccobacilli with bipolar stain uptake are seen in more than 70% of cases. First-line treatment of pneumonic plague is with streptomycin or gentamicin. Mortality approaches 100% without administration of antibiotics within 24 hours of overt signs of infection.

BOTULISM

Botulinum toxin is the most potent poison known. It is produced by the gram-positive, anaerobic, spore-forming bacillus, *Clostridium botulinum*. Food contamination and aerosolization are the likely mechanisms of a bioterrorist attack with botulism toxin. Once absorbed, the agent causes irreversible inhibition of presynaptic acetylcholine release. The classic clinical picture starts with cranial neuropahties, followed by descending flaccid paralysis resulting in diaphragmatic weakness and requirement for mechanical ventilation. Mental status, sensation, and body temperature are usually normal. Botulism is not transmitted from human to human.

A specific bioassay exists to confirm the diagnosis, and clinicians should suspect botulism in any patient with descending flaccid paralysis. Treatment is with supportive care, mechanical ventilation, and antitoxin (available from the CDC). Antitoxin therapy binds to circulating toxin and is most effective when it is given within 24 hours of the onset of neurologic signs. Antibiotic therapy does not improve outcomes in patients with aerosolized or food-borne botulism and does not play a role in this toxin-mediated bioterrorist threat. A pentavalent botulinum toxoid vaccine is currently under development.

TULAREMIA

Like anthrax and plague, tularemia occurs naturally as a zoonotic infection, transmitted by arthropods in rabbit, deer, and

---

2See References 6 and 7.
3See References 5 to 7.
squirrel reservoirs. Tularemia is caused by *Francisella tularensis*, a gram-negative coccobacillus that is a potential bioterrorism agent because of its extremely high infectivity, ease of spread, and significant morbidity. Only 10 organisms are required to cause pulmonary illness. Six forms of tularemia exist: glandular, ulceroglandular, oculoglandular, oropharyngeal, typhoidal, and pneumonic.

Aerosolized bacteria causing pneumonic tularemia would be the primary threat in a bioterrorist attack. The clinical syndrome of pneumonic disease can resemble a nonspecific viral illness, meningitis, or pneumonia. Respiratory failure and shock are far less common with tularemia than with inhalational anthrax or pneumonic plague. Although mortality of tularemia is lower than that of other diseases caused by category A agents, and even though human-to-human transmission does not occur, the ability of *F. tularensis* to cause illness after seemingly insignificant exposures is prodigious. Treatment is with aminoglycosides or fluoroquinolones, and postexposure prophylaxis is with fluoroquinolones or doxycycline.

### PATIENT TEACHING TIPS

Use the Centers for Disease Control and Prevention website ([www.bt.cdc.gov](http://www.bt.cdc.gov)) for further information about bioterrorism agents.

Finish postexposure prophylaxis completely.

Return immediately if you have worsening:
- Fever, chills, lightheadedness, fatigue
- Shortness of breath, cough
- Rash
- Headache, stiff neck

Tell your close contacts to be evaluated if they are symptomatic.

Stay home from work or school until you are beyond the incubation period of the suspected agent or no longer symptomatic.

Adapted from Reference 13.

### VIRAL HEMORRHAGIC FEVERS

Viral hemorrhagic fevers (VHFs) represent a group of zoonotic diseases caused by RNA viruses that are currently geographically isolated to specific world regions. The dearth of vaccines, postexposure prophylaxis, and treatment options combined with high mortality rates would make these agents especially dangerous if they were weaponized in a bioterrorist attack. The characteristics of the individual viruses are listed in Table 182.2. Clinical features common to all VHFs include fever, myalgias, headache, and rash. Most patients exhibit thrombocytopenia, leukopenia, and either renal or hepatic failure (Table 182.3). The diagnosis is made by serologic testing or viral culture. Treatment is purely supportive, although ribavirin may provide some benefit. Mortality ranges from 1% for dengue to almost 90% for Ebola hemorrhagic fever.

Infections of the small intestine. Given the predominant location of this region can lead to large-volume, watery diarrhea. Because the high secretory capabilities of the small intestine, infections tend to be felt in the lower quadrants, and in some cases they may mimic appendicitis, with focal right lower quadrant pain.

Small bowel and large bowel are both susceptible to toxin-producing organisms that induce diarrhea through direct damage to the epithelium, thereby disrupting the regulation of fluid balance. Because the lactate enzyme responsible for breakdown of lactose is present primarily in the epithelial surface, any infection that causes significant epithelial damage may lead to temporary lactose intolerance. Whereas bacterial toxin-induced diarrhea tends to be isotonic, virally induced diarrhea causes losses primarily of sodium, potassium, and bicarbonate.

Food- and Water-Borne Infections

David K. Zich

**KEY POINTS**

- In patients who develop clinical illness from food-borne and water-borne pathogens, most symptoms resolve spontaneously without intervention.
- Significant mortality does occur. Each year, thousands of people in the United States and millions of people in developing countries die of acute gastroenteritis.1
- Proper treatment can lead to significant relief for the patient, but inappropriate medications may complicate the clinical picture, lengthen the carrier state, or trigger potentially life-threatening conditions.
- Developing a systematic approach to gastrointestinal disease is essential to eliminate unnecessary testing and to restore health as quickly as possible while minimizing adverse and dangerous effects of intervention.

**PATHOPHYSIOLOGY**

The portion of the gastrointestinal tract affected by food- and water-borne illnesses depends on the pathogen. Staphylococcal food poisoning is caused by a toxin that has no effect on the intestinal mucosa. Instead, once absorbed, the toxin acts directly on nausea centers in the brain and thus causes severe nausea and vomiting.

Infections of the small intestine may disrupt ionic exchange and result in increased chloride secretion and sodium retention within the bowel lumen. Water follows, thereby overwhelming absorption capacity, and diarrhea ensues. Viruses create diarrhea by distorting the epithelium and interfering with absorptive capabilities. This process results in loss of fluid, electrolytes, and, in some cases, fats and sugars. Because of the high secretory capabilities of the small intestine, infection of this region can lead to large-volume, watery diarrhea. In patients with large fluid losses, significant electrolyte disturbances and acidosis may occur, more commonly with infections of the small intestine.5 Given the predominant location of the small intestine, cramping and discomfort are localized more often to the upper abdomen.

Invasive organisms primarily affect the distal ileum and large intestine. Common invasive organisms include *Campylobacter, Salmonella, Shigella, Yersinia,* and *Entamoeba histolytica*. These pathogens penetrate the intestinal lining and create an intense inflammatory response. This process results in losses of fluid and, in some cases, varying amounts of blood. The large intestine has less secretory function. Therefore, infections of this region are more likely to cause smaller, frequent episodes of diarrhea that is more apt to contain mucus or blood when compared with small intestine infections. Severe alterations in electrolytes and acid-base balance are less common. Symptoms of large intestine infections tend to be felt in the lower quadrants, and in some cases they may mimic appendicitis, with focal right lower quadrant pain.

Small bowel and large bowel are both susceptible to toxin-producing organisms that induce diarrhea through direct damage to the epithelium, thereby disrupting the regulation of fluid balance. Because the lactate enzyme responsible for breakdown of lactose is present primarily in the epithelial surface, any infection that causes significant epithelial damage may lead to temporary lactose intolerance. Whereas bacterial toxin-induced diarrhea tends to be isotonic, virally induced diarrhea causes losses primarily of sodium, potassium, and bicarbonate.

**PRESENTING SIGNS AND SYMPTOMS**

Presenting signs and symptoms vary widely, depending on the pathogen causing the disease. Many parasites that infect the intestines cause no discernible symptoms. Asymptomatic chronic bacterial carrier states can occur in otherwise healthy individuals. When symptoms do occur, they are limited in most patients to vomiting and diarrhea of varying degrees. Rarely, patients have more systemic symptoms. *Listeria monocytogenes* infections, more common in pregnant women, cause fever, myalgias, headache, and neck stiffness. Scombroid poisoning from fish can cause symptoms of a severe allergic reaction, and ciguatera poisoning, also from fish, can cause neurologic symptoms including severe paresthesias and dysesthesias.

Although food containing preformed toxins can cause illness within 1 to 6 hours, most acute gastroenteritis has at least a 12- to 48-hour incubation period (Table 183.1). Typically, the onset is gradual and is often noticed as mild dyspepsia after eating a meal. This is the meal often suspected by the patient to be the cause of the illness. However, the
pathogen has usually been incubating for the last 1 to 2 days and is just starting to cause symptoms.

Within 1 to 2 hours after the initial dyspepsia, nonbloody vomiting often begins. If bleeding does occur, the most common cause is a Mallory-Weiss tear. This results when forceful ejection of gastric contents creates a tear in the mucosa at the junction of the esophagus and the stomach. It rarely occurs during the first episode of vomiting, and treatment is almost always supportive. An initial presence of blood, or a persistent predominance of gross blood, should prompt a search for noninfectious causes of vomiting such as a bleeding peptic ulcer or esophageal varices.

Diarrhea can occur simultaneously with vomiting, or it may be delayed for up to 48 hours after vomiting begins. In some cases, diarrhea may be the only component of clinical illness. Gross diarrheal blood is more common than hematemesis and varies by pathogen (Box 183.1). Dysentery, defined as a diarrheal stool containing gross blood, can be accompanied by fever, abdominal pain, and tenesmus.

**DIFFERENTIAL DIAGNOSIS**

Vomiting and diarrhea can result from other pathologic states, or they may be iatrogenic, such as from a medication side effect. Vomiting and diarrhea can herald an endocrine emergency such as in adrenal crisis, or they may represent a completely benign event, such as diarrhea after long-distance running. Maintaining a level of suspicion for other causes is essential, to minimize the chance of missing a more dangerous disorder or to reassure a patient when the cause is benign. The following subsections describe additional diagnoses to consider.

**VOMITING AND DIARRHEA**

**Toxic Ingestions and Overdoses**

Accidental or intentional ingestion of toxic chemicals or medication overdoses frequently manifest with abdominal pain, nausea, vomiting, and sometimes diarrhea. Depending on the situation, patients may not be forthcoming with an accurate history unless they are specifically questioned.

**Prescription Drugs**

Nausea, vomiting, and diarrhea are some of the most common side effects of many different prescriptions drugs, from antibiotics to chemotherapy agents. Patients with acquired immunodeficiency syndrome (AIDS) often take antiviral medications that cause such a high incidence of vomiting that antinausea medications are prescribed prophylactically. A careful history of new medications or changes in dose will help rule out medications as a cause.

**Opiate Withdrawal**

Nausea and vomiting are quite common in acute opiate withdrawal. In addition, a patient usually experiences agitation,
diffuse aches, and diaphoresis. Patients experiencing opiate withdrawal often have hypertension along with tachycardia and tachypnea. Patients may not always admit their illicit drug use, thus making the diagnosis more challenging.

**Malignant Disease**

Brain tumors cause vomiting through neurogenic activation of the vomiting centers of the brain, usually in conjunction with increases in intracranial pressure. Gastric cancers lead to nausea and vomiting in advanced stages as gastric plasticity decreases. Infiltrative malignant diseases such as Kaposi sarcoma and lymphomas, especially in immunocompromised patients, can invade the intestinal wall and cause diarrhea. Colon cancers usually do not manifest with diarrhea until very late in the course when they obstruct solid matter, and liquid flows around the obstruction. Patients usually report gradual difficulty moving their bowels long before diarrhea begins.

**Irritable Bowel Syndrome**

Irritable bowel syndrome manifests predominantly as either constipation or diarrhea, sometimes accompanied by diffuse, crampy abdominal pain, although it rarely involves vomiting. Fever is absent, and no blood should be seen in the stool unless hemorrhoids are present. Patients may have a history of a stressful trigger, and they can often tell what is typical for a flare of this syndrome.

**Inflammatory Bowel Disease**

Inflammatory bowel disease flares usually manifest with gradually worsening abdominal pain and diarrhea, often bloody. Vomiting is less likely unless significant bowel stricture occurs in patients with Crohn disease.

**VOMITING WITHOUT DIARRHEA**

Vomiting is a symptom and not a diagnosis. Gastroenteritis can be diagnosed only if signs of gastritis enteritis are clearly present, based on clinical evaluation. Vomiting can also be caused by many toxic and metabolic disorders and organ dysfunction. Ingestions, carbon monoxide, and other poisonings often incite vomiting without other signs. Early hepatitis, biliary disease, and early appendicitis may cause vomiting, with few other signs. Other important causes of isolated vomiting include those discussed in the following paragraphs.

</table>
Obstruction
A history of abdominal surgery should raise suspicions of a possible intestinal obstruction. On physical examination, abdominal distention is common, and hypactive, high-pitched bowel sounds are in contrast to the hyperactive bowel sounds usually found in gastroenteritis.

Cyclic Vomiting
The challenge in patients with cyclic vomiting is in determining the rare episode when the symptoms may be caused by gastroenteritis, instead of being an exacerbation of the underlying disorder. Diarrhea is rare, fever should not be present, and a history of stressful triggers is often identifiable when the episode results from an exacerbation of cyclic vomiting.

Intracranial Disease
Headache is a common complaint that often accompanies acute gastroenteritis. However, vomiting also frequently occurs simultaneously with headaches caused by migraines, intracranial hemorrhage, or tumor. When the history of a headache is elicited, the physician must consider the following factors so that more dangerous disease is not overlooked. Headache that started before the onset of vomiting, or headache as the primary focus of the patient, is concerning. Similarly, a sudden, severe headache occurring while vomiting may indicate an aneurysmal rupture resulting from increased intracranial pressure during the Valsalva maneuver.

Myocardial Infarction
Atypical presentations of myocardial infarction are important to recognize. Vomiting without diarrhea in a patient with significant risk factors should prompt consideration of a cardiac cause. The concomitant presence of shortness of breath and diaphoresis, with or without chest pain, further increases the probability of myocardial infarction.

Early Pregnancy
“Morning sickness” is most common within the first 13 weeks of gestation. However, pregnancy-associated nausea and vomiting may be more severe at other times of day and may continue well past the first trimester. Not unusually, vomiting is the first symptom a woman experiences before she is aware of the pregnancy. Vomiting without diarrhea, symptoms spanning several days, and hunger between episodes should arouse suspicion of pregnancy as the cause. Inquiring about breast tenderness and missed or irregular menstrual periods can help to elicit the diagnosis. A pregnancy test should be standard in the evaluation of any woman of childbearing age who presents with symptoms of acute gastroenteritis.

FOCAL PAIN
 Patients with acute gastroenteritis often complain of abdominal pain, but the quality of this pain tends to be crampy and migratory secondary to increased intestinal motility and spasm. Mild, constant midepigastric pain is also common after vomiting because of gastritis and abdominal wall muscle exertion. In rare cases, Campylobacter and Yersinia may cause isolated cecitis, characterized by focal right lower quadrant pain in the absence of vomiting or diarrhea that mimics acute appendicitis. Severe, focal, unrelenting pain should prompt a search for other causes, however.

Focal Inflammation
Causes of focal inflammation including gastritis, pancreatitis, cholecystitis, diverticulitis, and appendicitis are suspected when pain is isolated to these respective areas.

Gynecologic Emergencies
These conditions include tubo-ovarian abscess, ovarian torsion, ruptured ectopic pregnancy, and pelvic inflammatory disease. A pelvic examination and pregnancy test are essential in the evaluation of women who complain of concomitant pelvic or lower abdominal pain.

DIFFUSE PAIN
Perforated Viscus
A history of peptic ulcer disease, recent gynecologic or gastrointestinal instrumentation, or fever with peritoneal signs should raise the suspicion of perforated viscus.

Ischemic Bowel
In patients with risk factors for peripheral vascular disease, diffuse abdominal pain along with nausea and diarrhea after eating may indicate compromised blood flow to the intestines. The onset may be more gradual in patients with slowly progressive atherosclerosis, or it may be abrupt from an embolic event to the intestinal vasculature. The physical examination is often unimpressive, given the severity of the stated discomfort (hence the finding of “pain out of proportion to examination”). A high index of suspicion should be maintained, especially in the older population, because missing the diagnosis can lead to significant morbidity and even death.

DIAGNOSTIC TESTING
Diagnostic testing is often overused in infectious gastroenteritis. With symptoms lasting less than 24 hours in otherwise healthy individuals who are not at the extremes of age, no diagnostic testing is indicated, other than a pregnancy test in women of reproductive age. Exceptions include patients with severe symptoms, multiple grossly bloody stools, or hemodynamic instability, as well as testing for epidemiologic purposes if food poisoning or a bioterrorism event is suspected.

Laboratory or radiologic evaluation may be helpful in several situations. A bedside urine evaluation for ketones may be useful to document dehydration and to guide intravenous fluid management. In patients whose symptoms have persisted for more than 24 hours, electrolyte determinations and tests of kidney function may be indicated. If a chemistry panel is obtained, calculation of the anion gap should be done to prevent missing clues to diabetic or alcoholic ketoacidosis, toxic ingestions, or other serious conditions. Mild elevations in liver function tests are very nonspecific in acute gastroenteritis, but marked elevations could be an indication of hepatitis A infection.

Although the diagnostic yield is generally low, stool culture in patients who have unrelenting diarrhea may detect a treatable cause that can significantly shorten the course of illness. Typically, positive results take at least 2 to 3 days, and symptoms have often resolved by the time results return. For patients who develop diarrhea 3 days or more after being
hospitalized, bacterial stool cultures have not been found to be helpful. Testing for ova and parasites has not shown to be cost effective unless the patient is at identifiable risk. This group includes patients with diarrhea persisting for several days after international travel to endemic regions, persons who ingest untreated water while camping or hiking, those with exposure to daycare centers, men who have sexual contact with other men, and persons who have sexual contact with patients with AIDS. If parasitic infection is suspected, three separate specimens from different time periods must be sent for ova and parasites before the test can be considered negative. Clostridium difficile testing should be performed for anyone with persistent diarrhea and a history of antibiotic use in the previous 3 months. In patients with severe diarrhea, C. difficile testing should be considered even in the absence of recent antibiotic exposure or recent hospitalization. The reason is the emergence of a hypervirulent strain, designated NAP1/BI/O27, that has caused illness in otherwise healthy individuals without the traditional risk factors for C. difficile colitis.

The recommended diagnostic work-up in patients with AIDS and in others who are severely immunocompromised is more aggressive. Studies in these patients tend to yield more positive results, and symptoms are less apt to resolve without intervention. Stool should be sent for culture just as in immunocompetent patients. C. difficile testing should be performed because this remains the most common pathogen detected in patients with human immunodeficiency virus infection and diarrhea. Three separate specimens should be sent to be examined for ova and parasites, given the intermittent shedding of organisms. In addition, stool should be sent for acid-fast smear to detect Cryptosporidium, Isospora, and Cyclospora. Finally, in severely immunocompromised patients with a CD4 count lower than 100 cells/microliter, a trichrome stain should be ordered to test for microsporidium. Unlike in immunocompetent patients, in whom blood cultures are of extremely limited use, blood culture results in immunocompromised patients may be positive in up to 40% of cases and may yield a diagnosis even in the absence of positive stool culture results. Fungal blood cultures should also be considered, to detect Mycobacterium avium complex. In this population, if severe diarrhea persists despite negative evaluations, the patient will need endoscopic evaluation for mucosal biopsy and additional cultures.

For patients with severe abdominal pain or distention, an obstructive plain radiographic series or abdominal computed tomography scan with oral and intravenous contrast can help to differentiate other more serious causes of their symptoms. Abdominal computed tomography scans without contrast, or with oral contrast alone, may be sufficient, depending on the experience of the radiologist conducting the examination.

A complete blood count is usually of little value, with rare exceptions. The stress of vomiting often causes transient leukocytosis that does not correlate with the severity or cause of illness. Hemoglobin and hematocrit determinations may be helpful in patients with hemorrhagic diarrhea for assessment of anemia. Eosinophilia may indicate an allergic or parasitic origin. Macrocytic anemia can occur with infection involving Diphyllobothrium latum, and low platelet counts can be seen in infections such as Q fever (Coxiella burnetii).

In patients with an acute onset of vomiting and diarrhea, documentation of gross blood in the stool is helpful. Checking for occult blood has not been proven to be sensitive or specific. When gross blood is absent, hemoccult testing provides little to no insight into the causative pathogen and should not be used to guide treatment. Similarly, fecal leukocyte testing has low sensitivity and specificity and should not be used to justify empiric antibiotic treatment.

To reiterate, most cases occur in young, otherwise healthy individuals who have had symptoms for less than 24 hours. In this population, minimal to no testing should be the rule.

**TREATMENT AND DISPOSITION**

Emergency treatment of gastroenteritis begins with airway, breathing, and circulation. Airway and breathing are rarely an issue unless large-volume hematemesis is present. Boerhaave syndrome, disruption of esophageal varices while vomiting, and severe cases of anthrax are some of the few causes of massive hematemesis.

If the patient is hemodynamically unstable, immediate intervention is required. The patient should receive fluid resuscitation with two large-bore intravenous catheters or a central line, and the physician should consider causes of illness other than simple gastroenteritis. If the patient has a recent history of international travel, review of the previous location’s endemic pathogens is essential. Countries such as Haiti have had outbreaks of cholera (Vibrio cholerae) that can lead to circulatory collapse in as little as 24 hours.

For patients who have severe allergic symptoms after ingesting fish and scombroid is suspected, treatment should be initiated with antihistamines.

For patients experiencing neurologic symptoms such as paresthesias, dysesthesias, reversal of hot and cold sensation, or even altered mental status after eating fish, ciguatera poisoning should be suspected. Although not universally accepted, mannitol, 1 g/kg of a 20% solution over 30 minutes, has dramatic effects on improving symptoms.

Most patients are stable, however, and are suffering from nausea, vomiting, crampy abdominal pain, and possibly diarrhea without other significant symptoms. For this group, the mainstays of treatment consist of rehydration and alleviation of symptoms through antiemetics (Fig. 183.1). The use of empiric antibiotics is not indicated in most cases.

For those patients who are hemodynamically stable and whose vomiting can be controlled, oral rehydration is adequate and is often greatly underused. Ketonemia has been implicated in gastroenteritis. In patients with significant dehydration, nausea and vomiting may continue because of circulating ketones long after the initial infectious cause has been eradicated by the body. In this circumstance, proper administration of intravenous fluids may be all that is required to resolve the patient’s symptoms. If a patient is unable to tolerate oral intake, intravenous normal saline solution is adequate for initial hydration. For patients with significant ketosis, switching to dextrose-containing compounds after initial rehydration may help to restore normal metabolic function more quickly.

Many choices of antiemetics and routes of administration are available. When choosing a medication, one should consider pregnancy class, cost, and side effects, particularly the extrapyramidal side effects of the phenothiazines and...
metoclopramide. Table 183.2 gives the characteristics of common antiemetic agents. If one agent fails, a switch to a different class of agent is recommended, rather than repeat administration of an agent of the same class.

The hazards of using antidiarrheal agents in acute gastroenteritis appear to have been overstated. For afebrile patients without grossly bloody diarrhea or a high suspicion of C. difficile colitis from recent antibiotic use, antimitotility agents such as loperamide or atropine-diphenoxylate can be safely administered. Use of these drugs is recommended for large-volume diarrhea that compromises hydration status or is otherwise hindering a patient’s ability for self-care.

Antibiotics are rarely indicated in the empiric treatment of acute gastroenteritis, for many reasons. Viruses remain the most common causes of acute gastroenteritis in the general population, and these infections resolve without intervention. Most bacterial causes are self-limited and are eradicated by the host defenses in a short time. Common adverse reactions of most antibiotics are nausea or diarrhea, occurring in up to 10% of patients. Although certain antibiotics are more prone to causing C. difficile colitis, any antibiotic can predispose patients to this complication. Administering antibiotics to patients with non-typhi Salmonella infections is ineffective and may lead to a prolonged carrier state. If the patient has contracted illness from Escherichia coli serotype O157:H7, antibiotics will have no effect on the symptoms but may lead to an increased incidence of hemolytic-uremic syndrome. Finally, empiric treatment with antibiotics contributes to the alarming development of resistant pathogens in the general patient population. Empiric antibiotics are usually ineffective, may complicate the picture, may even harm the patient, and contribute to the formation of resistant organisms.

*Laboratory evaluation should include BUN/Cr level (with calculation of the anion gap), general chemistries, and diarrheal stool (if available) for culture, ova and parasites, and C. difficile.

The indications for empiric antibiotics are very narrow. If a patient appears toxic, has a fever higher than 101°F and bloody diarrhea, or is hemodynamically unstable, antibiotics may be helpful. Grossly bloody diarrhea alone is not an indication for empiric antibiotic use, and again, bloody diarrhea may be caused by *E. coli* O157:H7. This serotype does not usually cause a fever, and therefore empiric antibiotics prescribed for grossly bloody diarrhea in conjunction with a temperature greater than 101°F should not raise concerns of inducing hemolytic-uremic syndrome.

Another indication for empiric antibiotics involves acute gastroenteritis in the setting of travel to areas endemic for traveler’s diarrhea. The most common pathogens include enterotoxigenic *E. coli*, *Shigella*, *Salmonella*, and *Campylobacter*. In many cases, prompt use of a fluoroquinolone can lead to relief of symptoms within hours. Unfortunately, resistance to this class of drugs and to many other antibiotics is rising throughout the world, and treatment failures are becoming more common. Of the foregoing pathogens, *Campylobacter* has a high enough resistance to fluoroquinolones that erythromycin is now the drug of choice in these infections. For continued empiric treatment of traveler’s diarrhea in patients who do not respond to fluoroquinolones, azithromycin may be used. Sending stool cultures before the initiation
of antibiotics can be helpful, given the high rates of resistance, in anticipation of potential treatment failures. Table 183.3 gives specific antibiotic regimens for symptomatic patients in whom the pathogen is identified.

In general, patients who are hemodynamically unstable at any point in their stay, who have persistent pain, or who continue to vomit frequently should be admitted until oral intake can be tolerated and pain improves. If a noninfectious origin has not been ruled out and symptoms continue, admission should also be considered. Patients with severe comorbid illness, and those who take multiple medications that would be affected by poor oral intake or malabsorption, may also need to be admitted.

Diabetic patients may be particularly challenged by acute gastroenteritis. Infection combined with an inability to take hypoglycemic medications may increase their blood glucose concentrations and may exacerbate their dehydration. Diabetic patients may become hypoglycemic, given their decreased intake in the setting of long-acting hypoglycemic medications, and physicians should have a low threshold for

admitting these individuals. If an insulin-dependent patient is discharged, a basal rate of insulin must be continued. Cutting the usual dose of insulin in half, or instructing the patient to take the long-acting insulin only and checking blood glucose levels regularly, may be sufficient. Discussion with the primary care physician before discharge facilitates outpatient management.

Patients with persistent nausea but no vomiting can usually be discharged with an antiemetic and careful instructions for maintaining hydration. Persistent diarrhea alone is not an indication for admission, unless the patient is immunocompromised and has significant dehydration on presentation.

Dietary recommendations are always of great concern to patients on discharge. Many complex regimens involve significant dietary restrictions, based on limited scientific data. Patients should be advised that the number-one priority is to stay hydrated. If solid foods do not sound appealing, then they should not be encouraged. For patients with mild diarrhea or persistent nausea, water or commercially available sports drinks should be used. These drinks are not properly balanced for more severe dehydration. If the patient is having large volumes of diarrhea or fluid losses, a balanced glucose and electrolyte solution with or without starches is recommended. Oral rehydration solutions are available in many pharmacies. An effective solution can be made at home by adding one-half teaspoon of salt, one-half teaspoon of baking soda, and four tablespoons of sugar to 1 L of water.

Once a patient becomes interested in solid foods, a bland diet of bananas, rice, apples, and toast (the BRAT diet) traditionally has been recommended. No data support the BRAT diet, and patients should be encouraged to eat small amounts of whatever appeals to them, with a few exceptions. Both caffeine and alcohol have direct stimulatory effects on the bowel and therefore may worsen symptoms. In addition, a few patients encounter temporary lactose intolerance after gastroenteritis. If dairy products exacerbate symptoms, then refraining from these products for 1 to 2 weeks should allow the intestines to restore their normal function.

**COMPLICATIONS**

Significant complications are fortunately quite rare following gastroenteritis. The following are important to keep in mind when treating a patient with current symptoms or a recent history of acute gastroenteritis.

**LACTOSE INTOLERANCE**

The most common minor complication is temporary lactose intolerance, which usually resolves spontaneously. As symptoms of the primary infection improve, patients may ingest milk products. However, if dairy products result in worsening bloating and cramping symptoms, then patients are advised to avoid these products for 1 to 2 weeks. Rarely does the intolerance become more chronic. Similarly, steatorrhea, or fat malabsorption, may occur transiently, particularly after a rotavirus infection, but it also resolves spontaneously.

**PROFOUND INTERNATIONAL NORMALIZED RATIO ELEVATIONS IN PATIENTS TAKING WARFARIN**

Case reports in patients taking warfarin have noted significant coagulopathies occurring in acute gastroenteritis. Although these disorders are usually associated with episodes lasting several days, one case occurred after a single day of diarrhea. The mechanism is presumed to be a decreased vitamin K level in the body, from both decreased oral intake and malabsorption within the intestine. Prothrombin time and international normalized ratio should be checked in patients taking warfarin, and close follow-up with repeat blood tests can prevent potential bleeding complications.
ESOPHAGEAL INJURY
Any patient who is forcefully retching may suffer a tear in the mucosal surface of the esophagus, called a Mallory-Weiss tear, and this can lead to blood in the vomitus. Patients usually have little to no associated pain, and bleeding almost always resolves spontaneously, but occasionally, endoscopic intervention is required to acquire hemostasis. A more serious complication results when complete transmural disruption occurs in the esophagus. Known as Boerhaave’s syndrome, it is usually accompanied by significant pain and is associated with a high mortality. A chest radiograph is almost always positive for mediastinal or intra-abdominal free air. Emergent surgical consultation and aggressive resuscitative management are essential.

BOWEL NECROSIS
Clostridium perfringens normally causes self-limited gastroenteritis. However, in rare cases, it can lead to enteritis necroticans, which rapidly progresses to shock and death.

DIABETIC KETOACIDOSIS
Diabetic patients may become significantly dehydrated in combination with high blood glucose levels, especially if these patients are unable to take their usual oral hypoglycemic agents. In severe circumstances, acute gastroenteritis may lead to diabetic ketoacidosis, coma, and death. A low threshold for electrolyte testing and measurement of the anion gap can help to detect the patient in danger of this complication.

NEUROLOGIC COMPLICATIONS
Campylobacter has been associated with a more severe form of Guillain-Barré syndrome that occurs even in patients with asymptomatic infections who have no signs of gastroenteritis. Most neurologic symptoms from ciguatera poisoning resolve in days to weeks, but some long-term dysesthesias have been documented up to 2 years later. Shigella can cause seizures and other neurologic symptoms, especially in children.

OTHER ORGAN SYSTEM INVOLVEMENT
Although rare, invasive bacterial pathogens have been associated with systemic complications such as cholecystitis, pancreatitis, meningitis, endocarditis, and osteomyelitis. Patients suffering from amebic colitis resulting from E. histolytica can develop a hepatic abscess. Bacillus anthracis may cause a spectrum of illness from minimal symptoms to shallow oral ulcers, massive lymphadenopathy with tissue edema, and fulminant upper and lower gastrointestinal bleeding. Severe cases of C. difficile colitis have led to protein-losing enteropathy with ascites and peripheral edema.

Skin and Soft Tissue Infections

Ellen M. Slaven

KEY POINTS

- Uncomplicated subcutaneous abscesses in otherwise healthy patients require incision and drainage alone, without antibiotic therapy.
- Cellulitis with induration may harbor a deep purulent collection despite the lack of fluctuance on physical examination. Ultrasound or needle aspiration may be used to assist in the search for areas of pus that require incision and drainage.
- Cellulitis with purulence should be treated with antibiotics that are active against community-acquired methicillin-resistant Staphylococcus aureus (CA-MRSA), and cellulitis without purulence should be treated with antibiotics active against Streptococcus species.
- Patients with mild diabetic foot infections may be treated with oral agents that target gram-positive organisms, including CA-MRSA.
- Emergency physicians must always search for signs of necrotizing infection to exclude the deadly diagnosis early in the management of skin and soft tissue infections.
- Emergency consultation with a surgeon is mandated when a suspicion of necrotizing skin and soft tissue infection arises.

COMMUNITY-ACQUIRED METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS

Since the late 1990s, an epidemic of skin and soft tissue infections has been caused by community-acquired methicillin-resistant Staphylococcus aureus (CA-MRSA). Currently in the United States, CA-MRSA is the most common cause of skin and soft tissue infection in patients presenting to emergency departments. Patients who develop these infections have been previously healthy, and most have not been exposed to health care settings or prior antibiotic therapy.¹

CA-MRSA is distinguished from hospital-acquired MRSA (HA-MRSA) not only by the location of acquisition, but also by the type of infection produced. HA-MRSA causes wound infections, sepsis, endocarditis, and metastatic infections, but CA-MRSA causes predominantly purulent skin infections. HA-MRSA rarely carries the Panton-Valentine leukocidin that is believed to be a potent virulence factor found in most CA-MRSA strains. In addition, HA-MRSA is generally resistant to many antibiotics, whereas CA-MRSA tends to be resistant predominantly to β-lactam agents but remains susceptible to many other antibiotics, such as trimethoprim-sulfamethoxazole and the tetracyclines. Unfortunately, the designation of these staphylococcal strains based on the site of acquisition has led to confusion now that newly developed CA-MRSA infections have been increasingly identified within hospitals.

In 2011, the Infectious Disease Society of America released its long-anticipated first clinical guidelines for the treatment of MRSA infections, including CA-MRSA, in adults and children. The panel of experts provided an evidence-based framework for the clinical evaluation and treatment of skin and soft tissue infections and more invasive infections such as bacteremia and pneumonia.

SUPERFICIAL SKIN INFECTIONS

IMPETIGO

Impetigo is most commonly encountered in preschool-age children. It is a superficial infection involving the epidermis and is highly contagious. Impetigo is readily spread from one site to another on one child and just as easily from one child to another. Two types of impetigo are recognized. The classic nonbullous impetigo begins with a vesicular lesion that becomes purulent. The vesicle then ruptures and reveals the typical, honey-colored crusted lesion. The face and extremities are commonly involved. Streptococcus pyogenes (group A Streptococcus) is the pathogen. The infection is self-limited and generally heals without scarring. Treatment is aimed at rapid resolution and prevention of transmission. The second type of impetigo, bullous impetigo, is caused by a toxin-producing strain of S. aureus. The appearance of bullous impetigo is of a flaccid, bullous lesion that may become filled with purulent fluid. Approximately 10% to 20% of all cases of impetigo are the bullous type.

Treatment with topical mupirocin is effective in patients with mild impetigo. Patients with more severe infections require systemic therapy with cephalaxin for 7 days. Azithromycin (500 mg orally on day 1, then 250 mg orally on days 2 to 5) is an alternative for patients who are allergic to...
penicillin. Empiric therapy for CA-MRSA bullous impetigo should be reserved for patients in whom this standard treatment fails.

**ERYSIPelas**

*S. pyogenes* is the primary pathogen responsible for the intradermal infection known as *erysipelas*, or Saint Anthony’s fire. This infection also involves the lymphatic drainage of the skin and produces a bright, erythematous raised area of skin. It is very well demarcated. The diagnosis is based on clinical appearance. The rash is common in older persons and in young children. Seventy percent of infections occur on the lower leg, and approximately 20% of infections occur on the face. The onset is quite sudden, fever may be present, and the rash is frequently very painful.

The drug of choice is penicillin. Admission to the hospital for intravenous antibiotics and supportive care may be indicated for patients who suffer from serious comorbidities or for patients who appear toxic. Azithromycin is an alternative agent. Always examine the feet carefully for signs of fissuring and include topical antifungals for treatment of tinea pedis because fissures may be a portal of entry for streptococci.

**Cellulitis**

*Cellulitis* results from bacterial infection of the dermis and the subcutaneous fat. Infection may arise following the entry of bacteria into the dermis through small breaks in the skin, larger wounds, or preexisting dermatitis. The infection may be limited to a small patch, or it may spread to include extensive areas of skin. Cellulitis is manifested by erythematous, warm, tender regions of skin that frequently spread. Lymphangitis and lymphadenitis may be present. Fever, chills, and malaise are common associated symptoms.

The pathogens of cellulitis are rarely identified in any particular patient, but they are thought to be primarily *S. pyogenes* (less commonly, other β-hemolytic streptococci such as groups B, C and G) and *S. aureus*. Culture of material aspirated from the involved skin is not routinely performed because of the invasive nature of the procedure and the low diagnostic yield. Blood cultures are of little value; only approximately 2% to 5% of these cultures yield results. A newer distinction has been proposed between nonpurulent cellulitis, which is believed to be more likely caused by *Streptococcus* species, and cellulitis that is associated with purulence and is probably caused by *S. aureus*. (See the later discussion of purulent skin infections.)

Patients with mild cases of nonpurulent cellulitis may be treated on an outpatient basis with an antibiotic effective against *Streptococcus* species such as cephalaxin or dicloxacillin. The precise length of therapy is determined by the patient’s response to therapy. A 5- to 10-day course of antibiotics is recommended. Empiric coverage for CA-MRSA should be reserved for patients who do not respond to β-lactam agents.

In patients with cellulitis who require hospital admission (e.g., those with extensive disease or underlying immunocompromises those who appear toxic), blood cultures are often obtained. Although the diagnostic yield of blood cultures is quite low, these cultures may provide useful information for patients who are significantly ill. Radiography may provide valuable information about patients with significant cellulitis, in particular to establish the presence of gas or foreign bodies. Patients with nonpurulent cellulitis who require admission may be treated with intravenous antibiotics, such as oxacillin, nafcillin, or cefazolin. For patients allergic to penicillin, azithromycin or levofloxacin may be substituted. Empiric coverage for CA-MRSA may be reserved for patients who do not improve during β-lactam therapy.

**Purulent skin infections**

Small, superficial pustular infections arising from the hair follicle are usually caused by *S. aureus* and are referred to as *folliculitis*. The lesions of folliculitis tend to be approximately 2 to 5 mm in diameter, they are isolated to the epidermis, and they generally produce pruritus rather than pain. Treatment consists of warm, moist compresses and topical antibiotic ointment, such as mupirocin. If systemic therapy is desired (because of a lack of response to topical therapy, extensive infection, or the presence of underlying immunocompromising medical condition), an agent active against CA-MRSA is recommended (Table 184.1).

*Furuncles* begin as simple folliculitis and extend deeper into the subcutaneous tissue and surrounding dermis. Furuncles are also called boils or subcutaneous nodules. These painful lesions tend to erupt in areas with hairy skin, in particular the face, axilla, and buttock.

When multiple adjacent furuncles coalesce, a large, purulent mass develops in the subcutaneous tissues. This is a *carbuncle*. These lesions tend to occur in areas of overlying thick skin, such as the nape of the neck, back, and posterior thighs. Carbuncles appear as erythematous soft tissue masses, and they may contain several orifices capable of draining purulent material. Diabetes is a risk factor for the development of carbuncles. These lesions are quite painful and are frequently associated with fever.

Incision and drainage are required for both furuncles and carbuncles. Carbuncles generally require drainage in the

operating room to provide sufficient analgesia and complete drainage. Antibiotics are indicated in patients with furuncles that are complicated by surrounding cellulitis and in all patients with carbuncles, and the selected antibiotic should be active against CA-MRSA (see Table 184.1).

Subcutaneous abscesses are collections of purulent material in the subcutaneous tissues, and they may occur anywhere on the body. The overlying skin may be uninvolved and may appear intact, or it may be erythematous and indurated. A pustule may be noted, or the overlying skin may be thin and in various stages of breakdown as the purulence drains spontaneously. Cellulitis of the surrounding dermis may also be noted. Purulent material must be sought out in patients who have cellulitis with moderate induration because pus may lie deep beneath the surface, without any signs of pustules or fluctuance. Ultrasound scanning or aspiration with a large-gauge needle (following local anesthesia) may reveal occult purulent collections. Incision and drainage are required for all subcutaneous abscesses. Antibiotics are not indicated for uncomplicated subcutaneous abscesses in healthy patients. The indications for antibiotic use are listed in Table 184.2.

Recurrent subcutaneous abscesses are common in this era of CA-MRSA. All patients should be educated regarding proper wound care, including keeping the incision site covered with a clean and dry bandage, regular hand washing, cleaning of surfaces that may become contaminated in the home, and avoiding shared personal items, such as razors. Attempts at decolonization may be beneficial for patients with recurrent abscesses or when intrapersonal transmission occurs within a household. These efforts, however, may be more successful after the patient has recovered and no longer has an open moist wound that may likely continue to harbor staphylococci. Regimens for decolonizing are not clearly defined. Some experts recommend intranasal mupirocin, twice daily for 5 to 10 days, in conjunction with daily chlorhexidine body washes for 5 to 10 days. Oral antibiotic therapy is not recommended for decolonization.

For outpatient management in patients with purulent cellulitis, empiric therapy with an agent active against CA-MRSA is recommended (see Table 184.1). The high cost of linezolid makes it a less desirable choice.

Intravenous vancomycin (15 to 20 mg/kg/dose actual body weight every 8 to 12 hours, not to exceed 2 g per dose) is the drug of choice for patients admitted with purulent cellulitis. Alternatives include clindamycin (600 mg orally or intravenously [IV] three times a day), linezolid (600 mg orally or IV twice daily), daptomycin (4 mg/kg/dose IV once daily), or telavancin (10 mg/kg/dose IV once daily).

No scientific data exist to support the routine culturing of purulent skin infections. Most patients improve with antibiotic therapy and incision and drainage, and microbiologic data are unnecessary. Most experts agree that cultures should be obtained when patients present with serious infections, when a course of outpatient antibiotics has failed, or when infections are complicated by underlying immune compromise, thus requiring hospitalization.

### DIABETIC FOOT INFECTIONS

With more than 16 million diabetic patients in the United States and a 3-year incidence of foot ulceration of 6% among them, emergency physicians are likely to treat many patients with diabetic foot infections. The ulcers may begin as small lesions, but these sites are prone to infection and are associated with great morbidity and mortality. Fifteen percent of diabetic patients with foot ulcerations require amputation, and the 3-year mortality is almost 30%.

Diabetic foot infections are diagnosed by their clinical appearance. Laboratory testing and radiography may be helpful to support the presence of infection or to define complications. The white blood cell count and erythrocyte sedimentation rate may be elevated in the presence of infection, but these tests are neither sufficiently sensitive nor definitively specific. Blood glucose testing is important because infections often lead to hyperglycemia. Uremia is known to impair healing. Radiographs may reveal the bony changes of osteomyelitis or subcutaneous gas produced by a necrotizing infection.

Obtaining a sample for microbiologic testing is worthwhile, particularly in the setting of severe infection. Swabbing the surface of an infected ulcer, or capturing purulent material as it makes its way to the surface, is likely to result in culture of contaminating bacteria, not necessarily the offending pathogen. Aspiration of deep-lying purulent material and sampling of tissue obtained during débridement are superior methods of acquiring material for microbiologic testing. The management of diabetic foot infections is directed by the severity of infection. Emergency physicians must assess the extent and depth of infection and the presence of foreign bodies or necrosis.

Aerobic gram-positive cocci, in particular S. aureus, including CA-MRSA, are the most predominant pathogens in diabetic foot infections. Patients with mild infections, defined as superficial when the lesions have less than 2 cm of surrounding cellulitis and are lacking abscess or necrosis, may be treated with antibiotics targeting S. aureus, including CA-MRSA (see Table 184.1). Moderate to severe infections tend to be caused by gram-positive cocci in addition to gram-negative bacilli and anaerobes. Moderate infections are defined as those with cellulitis extending more than 2 cm,
lymphangitis, spread to deep tissues, or the presence of abscess or necrosis. Severe infections cause systemic toxicity, including features such as fever, hypotension, confusion, acidosis, or azotemia. Empiric therapy for these polymicrobial infections requires a broad-spectrum regimen until the results of microbiologic culture are available. When a limb- or life-threatening infection is present, imipenem and vancomycin or linezolid are recommended (Table 184.3). Surgical consultation should be considered for all diabetic patients with foot infections that may be complicated by abscess or necrosis.

Necrotizing skin and soft tissue infections comprise a group of potentially limb- and life-threatening diseases caused by various virulent pathogens. The common theme is infection leading to ischemia and necrosis of skin, subcutaneous tissue, fat, fascia, and even muscle. These infections are also characterized by their capacity to progress rapidly. During the initial presentation of patients with necrotizing skin and soft tissue infections, emergency physicians are not able to discern the depth of the infection precisely, nor can they identify the particular pathogen or pathogens. The most important component of the emergency physician’s initial evaluation is to detect, or at least suspect, the presence of necrosis based on clinical findings alone. Be cautious when intense, localized pain is otherwise unexplainable, and consider the presence of an infection. Early use of antibiotics and consultation with surgeons may allow for lifesaving surgical débridement.

Gas gangrene, or clostridial myonecrosis, is the classic necrotizing skin and soft tissue infection. It often develops after a wound is contaminated with soil containing Clostridium perfringens. Another virulent bacterium, Vibrio vulnificus, can also cause necrotizing soft tissue infections. Particularly during warm months, V. vulnificus may cause infections in patients with wounds that are exposed to salt or brackish waters. Additionally, S. pyogenes can produce necrotizing soft tissue infections in previously healthy patients.

Many patients with necrotizing skin and soft tissue infections are found to be infected with multiple pathogens. An example is Fournier gangrene. This highly lethal infection of the perineum is commonly diagnosed in men with diabetes. This infection tends to be “mixed” because several pathogens, such as Streptococcus species, Enterobacteriaceae, and anaerobes (e.g., Bacteroides species), are recovered from culture.

When a necrotizing skin and soft tissue infection is suspected, no diagnostic testing, in particular imaging studies, should delay consultation with a surgeon. Although many diagnostic imaging studies have been employed in attempts to confirm and exclude necrotizing skin and soft tissue infections, none is superior to surgical exploration. A plain radiograph may demonstrate the presence of gas within the tissues, but it does not exclude a diagnosis of necrosis. Ultrasound scanning and computed tomography may identify gas within the tissues, in addition to deep-seated abscesses. Computed tomography and magnetic resonance imaging may show edema in the subcutaneous tissues or muscle and enhancement of inflamed fascia. None of these studies are adequately sensitive to exclude the presence of necrosis.

The definitive diagnosis of necrotizing skin and soft tissue infection is made by surgical exploration with direct visualization of the affected tissues and histologic examination of a frozen section biopsy specimen. Early surgical débridement is the definitive therapy.

Microbiologic studies, including blood cultures and culture of purulent material aspirated from a deep source, are indicated. Simply obtaining a swab from an open wound is likely to yield only contaminating bacteria. Infected tissue and fluids obtained during surgical débridement should also be cultured.

Antimicrobial therapy is vitally important early in the management of necrotizing skin and soft tissue infections. Antimicrobial therapy alone without surgical débridement leads to a mortality rate approaching 100%.

Surgical consultation must be obtained as soon as the presence of a necrotizing soft tissue infection is suspected. Box 184.1 lists common clinical indicators that mandate surgical consultation.

Early empiric antimicrobial regimens require broad-spectrum antimicrobial activity, including coverage for gram-positive, gram-negative, and anaerobic bacteria, and for pathogens with multidrug resistance, such as MRSA. No excellent options for monotherapy are available in this setting. Tigecycline is a broad-spectrum intravenous agent that is active against gram-positive, gram-negative, and anaerobic bacteria, including MRSA, but it is not as effective against Pseudomonas species, and safety concerns have limited its utility in this setting. Combination regimens include the...
skin and soft tissue infections, in particular streptococcal and
clostridial infections. All patients with necrotizing skin and
soft tissue infections, even those with suspected yet unproven
infections, should be admitted to the hospital for intravenous
antibiotic therapy and surgical evaluation.

  - Crepitus
  - Hemorrhagic bullae
  - Ecchymosis
  - Necrotic or black tissue

The proper selection of antibiotic therapy in the setting of the emergency department (ED) is often complicated. The offending pathogen is rarely known with certainty, and emergency physicians must contend with diseases caused by emerging microbes, such as human immunodeficiency virus and the coronavirus that causes sudden acute respiratory syndrome. Many common bacterial pathogens have developed novel antimicrobial resistance patterns, such as drug-resistant Streptococcus pneumoniae and Escherichia coli, and some well-known bacteria have developed new strains, such as community-acquired methicillin-resistant Staphylococcus aureus (CA-MRSA). Complicating this challenge is a perpetually growing list of new antimicrobial agents, and emergency physicians clearly must remain diligent to keep current with the ever-changing arena of infectious diseases that are frequently encountered in the ED.

Fortunately, many helpful resources are available, such as local hospital antibiograms and hospital-specific protocols. National guidelines such as the Surviving Sepsis Campaign and the Centers for Disease Control and Prevention (CDC) guidelines for sexually transmitted diseases provide helpful references. The annually updated Sanford Guide to Antimicrobial Therapy remains an invaluable up-to-date tool literally found within one’s pocket.

In general, antibiotic therapy is empiric, based on epidemiologic data of the most likely encountered pathogen. Critically ill patients benefit from early and appropriate antibiotic therapy and therefore initially require broad-spectrum therapy, unless a specific pathogen has been identified. Whenever possible, the safest, least expensive, and easiest to administer antibiotic should be prescribed. Oral therapy is preferable over parenteral, and single-dose regimens eliminate concerns regarding compliance when compared with multidose regimens.

Recommendations for antibiotic therapy in the ED for selected infectious diseases are outlined in the sections that follow.

**ODONTOGENIC INFECTIONS**

Penicillin (Pen Vee K, 500 mg orally [PO] four times daily for 5 to 7 days) is indicated for dentoalveolar abscesses, such as periapical abscesses. Clindamycin (300 mg PO four times daily for 5 to 7 days) is an alternative for penicillin-allergic patients. Significant abscesses (i.e., those causing facial swelling) require emergency drainage in addition to antibiotics. For patients admitted to the hospital with severe infection, ampicillin-sulbactam (1.5 g intravenously [IV] every 6 hours) is preferred. Clindamycin (900 mg IV every 6 hours) is again a suitable alternative.

**PHARYNGITIS**

Penicillin (Pen Vee K, 500 mg PO four times daily for 10 days) remains the drug of choice for group A streptococcal pharyngitis. A single intramuscular injection of benzathine penicillin (600,000 units if the patient’s weight is <27 kg and 1.2 million units if it is >27 kg) may be administered to enhance compliance. Patients with allergy to penicillin may be treated with azithromycin (500 mg PO on day 1, then 250 mg PO every day for 4 days). Group A Streptococcus has not developed resistance to penicillin, but approximately one third of isolates are resistant to macrolides or clindamycin. Linezolid (400 mg PO twice daily for 10 days) may be used for resistant strains.

**ACUTE SINUSITIS**

Mild symptoms of acute sinusitis may initially be treated with decongestants and analgesics. Reserve antibiotics for those in whom such conservative therapy fails and in patients with more severe symptoms, such as severe maxillary or facial pain and fever. High-dose amoxicillin is the preferred agent (adults: 1 g PO three times daily for 10 days; children: 90 mg/kg/day PO divided three times daily for 10 days).

**OTITIS EXTERNA**

Hydrocortisone, polymyxin B, and neomycin combined (Cortisporin otic, 4 drops in affected ear four times daily for 7 days) remain the standard therapy for otitis externa. If the tympanic membrane is perforated, a preferred combination of ciprofloxacin with hydrocortisone (3 drops in affected ear twice daily for 7 days) is indicated because of the ototoxicity of neomycin. Removal of debris from the ear canal promotes enhanced entry of the medication deep into the canal. When the canal is sufficiently swollen, a wick may need to be carefully placed to allow medication penetration.
SECTION XVII  INFECTIONS

Otitis Media

A prudent approach is to withhold antibiotics for 48 hours in afebrile children with otitis media who are more than 2 years old and are without pain. Treat with high-dose amoxicillin for 7 days (adults: 1 g PO three times daily; children: 90 mg/kg/day PO divided three times daily). Alternative therapy is with azithromycin (adults: 500 mg PO on day 1, then 250 mg PO every day for 4 days; children: 10 mg/kg [maximum, 500 mg] PO on day 1, then 5 mg/kg [maximum, 250 mg] PO every day for 4 days).

Acute Bacterial Meningitis

The treatment of acute bacterial meningitis is guided by epidemiologic risk factors; likely pathogens are determined primarily by the age of the patient and by exposure following trauma or surgical intervention. The goal of treatment is to administer antibiotics within 30 minutes of the patient’s arrival to the ED.

A Cochrane Review of more than 4000 patients with acute bacterial meningitis concluded that the use of adjunctive steroids decreases neurologic sequelae including hearing loss. Dexamethasone should be given intravenously 15 minutes before or concomitantly with the first dose of antibiotics and continued for 4 days (adults: 10 mg every 6 hours; children: 0.15 mg/kg every 6 hours).

Neonates (<1 month old): Combination treatment with ampicillin (200 mg/kg/day IV divided every 6 hours) and cefotaxime (300 mg/kg/day IV divided every 6 hours) targets the most common pathogens, which are group B Streptococcus, E. coli, and Listeria species.

Age 1 month to 50 years: Ceftriaxone (adults: 2 g IV every 12 hours; children: 100 mg/kg/day [maximum, 2 g] IV divided every 12 hours) with vancomycin (adults: 15-20 mg/kg [maximum, 2 g] IV every 12 hours; children: 15 mg/kg [maximum, 2 g] IV every 6 hours) provides coverage against S. pneumoniae (including penicillin-resistant strains), Neisseria meningitidis, and Haemophilus influenzae (although now rare because of the Hib vaccine).

Age greater than 50 years: Ampicillin (2 g IV every 4 hours), ceftriaxone (2 g IV every 12 hours), and vancomycin (15 to 20 mg/kg [maximum, 2 g] IV every 12 hours) are combined to cover S. pneumoniae, Listeria species, and gram-negative bacilli.

Postoperative/trauma: S. pneumoniae, S. aureus (including MRSA), and gram-negative bacilli (including Pseudomonas aeruginosa) are common pathogens in this setting; thus, cefazidime (2 g IV every 8 hours) combined with vancomycin (15 to 20 mg/kg [maximum, 2 g] IV every 12 hours) is recommended.

Community-Acquired Pneumonia

Both the Infectious Diseases Society of America and the American Thoracic Society provide guidelines for the management of community-acquired pneumonia. For outpatient management of otherwise healthy patients, azithromycin (500 mg PO on day 1, then 250 mg PO every day for 4 days) or doxycycline for 7 to 10 days (age > 8 years: 100 mg PO twice daily for 7 days) remains an excellent option.

If the patient has comorbid illness, then a respiratory fluoroquinolone (with enhanced activity against S. pneumoniae) is indicated, such as levofloxacin (750 mg PO every day), moxifloxacin (400 mg PO every day), or gemifloxacin (320 mg PO every day). Telithromycin is not recommended here out of concern for hepatotoxicity.

For inpatients, combination therapy is recommended for with ceftriaxone (2 g IV every 24 hours) and azithromycin (500 mg IV every 24 hours). Alternatives include intravenous respiratory fluoroquinolones levofloxacin (750 mg IV every day) or moxifloxacin (400 mg IV every day).

Pediatric Patients

Neonates with pneumonia require treatment for group B Streptococcus, Listeria species, and gram-negative bacilli. The combination of ampicillin (50 mg/kg IV every 12 hours) and gentamicin (2.5 mg/kg IV first dose) is recommended.

Children treated as outpatients require coverage for S. pneumoniae, and high-dose amoxicillin (100 mg/kg divided every 8 hours) is commonly used. An alternative is azithromycin (10 mg/kg [maximum, 500 mg] PO on day 1, then 5 mg/kg [maximum, 250 mg] PO every day for 4 days). If the patient is hospitalized, then use ceftriaxone (50 mg/kg IV every day) for children younger than 5 years. Add azithromycin (10 mg/kg [maximum, 500 mg] divided IV every 12 hours) if children are older than 5 years. For severe infection, add vancomycin (15 mg/kg IV every 6 hours).

Cholecystitis

Enterobacteriaceae such as E. coli and Proteus species are the most common pathogens in cholecystitis, as well as other biliary tract infections, and antibiotic selection must take into consideration adequate activity against these gram-negative bacilli. Other pathogens include anaerobes and enterococci. A regimen of piperacillin-tazobactam (3.375 g IV every 6 hours) alone or ciprofloxacin (500 mg IV every 12 hours) with metronidazole (1 g IV first dose) is recommended, in addition to surgical intervention.

Diarrhea (Dysentery)

Mild to moderate diarrhea is best managed with antimotility agents and fluids. Severe diarrhea (i.e., more than six unformed stools/day, the presence of fever, or bloody stools) is an
indication for antimicrobial therapy. Fluoroquinolones, either ciprofloxacin (500 mg PO twice daily) or levofloxacin (500 mg PO every day), remain the drugs of choice. Trimethoprim-sulfamethoxazole ([TMP-SMX] 1 double-strength [DS] tablet PO twice daily) is an alternative. All regimens are recommended for 3 to 5 days. If the patient has recently received antibiotic therapy and *Clostridium difficile* colitis is considered, then add metronidazole (500 mg PO three times daily) for 10 to 14 days.

**URINARY TRACT INFECTION**

Growing concern exists about widespread and increasing resistance of *E. coli* to TMP-SMX and ciprofloxacin. In 2009, the rate of resistance to each of these two agents was greater than 25% in many regions of the United States. Knowledge of local antibiotic resistance patterns in urinary pathogens may assist in the empiric treatment of urinary tract infections. TMP-SMX (1 DS tablet PO twice daily for 3 days) is the drug of choice if the local rate of resistance to TMP-SMX is less than 20%. Ciprofloxacin (250 mg PO twice daily for 3 days) or levofloxacin (250 mg PO every day for 3 days) is an alternative if the local rate of resistance to fluoroquinolones is less than 20%. (Moxifloxacin and gemifloxacin have low urinary concentrations and are not recommended.) An alternative for uncomplicated urinary tract infections is nitrofurantoin (100 mg PO four times daily for 7 days) or fosfomycin (3 mg PO once).

Pyelonephritis is initially treated with ciprofloxacin (500 mg PO twice daily for 7 days) or levofloxacin (250 mg PO every day for 7 days). Hospitalized patients may receive ciprofloxacin IV (400 mg PO twice daily) or levofloxacin (750 mg every day) for 14 days. Urinary cultures must be obtained to assess for possible resistance to fluoroquinolones. An alternative regimen is ampicillin (2 g IV every 6 hours) plus gentamicin (5 mg/kg IV every 24 hours), or piperacillin-tazobactam alone (3 g IV every 6 hours) for 14 days.

**SEPSIS**

Patients with sepsis who do not have a clear source of infections require early broad-spectrum antibiotics; the goal is intravenous antibiotic administration within the first hour of their presentation to the ED. Imipenem (500 mg IV every 6 hours) plus vancomycin (15 to 20 mg/kg [maximum, 2 g] IV every 12 hours) or piperacillin-tazobactam (4.5 mg IV every 6 hours) with vancomycin (15 to 20 mg/kg [maximum, 2 g] IV every 12 hours) is recommended. In penicillin-allergic patients, a combination of ciprofloxacin (400 mg IV every 12 hours), metronidazole (1 g IV every 12 hours), and vancomycin (15 to 20 mg/kg [maximum, 2 g] IV every 12 hours) may be prescribed.

Neonatal sepsis (<1 month of age) may be empirically treated with ampicillin (25 mg/kg IV every 8 hours) and cefotaxime (50 mg/kg IV every 12 hours). Vancomycin (15 mg/kg IV every 12 hours) should be added if MRSA is a potential concern.

Empiric therapy of childhood sepsis is with ceftriaxone (100 mg/kg in every 24 hours) plus vancomycin (15 mg/kg [maximum dose, 2 g] IV every 12 hours).

**CELLULITIS**

A newer paradigm has been proposed by the Infectious Diseases Society of America for the treatment of cellulitis in the era of CA-MRSA. This protocol is based on the detection of purulent material associated with cellulitis and the likely presence of CA-MRSA.

Dry cellulitis, or cellulitis not associated with exudates, purulence, or abscess formation, is likely caused by *β*-hemolytic streptococci, such as *Streptococcus pyogenes*, and should be treated with an antibiotic targeting these organisms; that is, cephalexin (500 mg PO four times daily) or dicloxacillin (500 mg PO four times daily) for 5 to 10 days. The precise duration of therapy should be dictated by the clinical response.

Cellulitis associated with an underlying abscess or with purulent exudates must be treated with an agent that is active against CA-MRSA, such as TMP-SMX (1 DS tablet PO twice daily), clindamycin (300 mg PO four times daily) or doxycycline (100 mg PO twice daily) for 5 to 10 days. Vancomycin (15 to 20 mg/kg [maximum, 2 g] IV every 12 hours) remains the drug of choice for patients requiring hospitalization. Clindamycin (900 mg IV every 8 hours) is an alternative. Linezolid (600 mg IV every 12 hours) is not recommended as first-line therapy, primarily because of its higher cost.

Skin and soft tissue infections that are limb- or life-threatening should be treated empirically with imipenem (500 mg IV every 6 hours) and vancomycin (15 to 20 mg/kg [maximum, 2 g] IV every 12 hours).

**MAMMALIAN BITES**

Prophylaxis against infection following the bite of an animal must provide coverage against *Pasteurella* species, *S. aureus*, and anaerobes. Amoxicillin-clavulanate (875/125 mg PO twice daily) is the primary oral agent and should be prescribed for 3 days. Dual therapy with clindamycin (300 mg PO four times daily) plus ciprofloxacin (500 mg PO twice daily), also for 3 days, is an alternative regimen for patients with penicillin allergy.

Outpatient treatment of an established soft tissue infection resulting from an animal bite may be implemented with the same antibiotics used for prophylaxis, only for a longer duration (i.e., 7 to 10 days). Patients hospitalized with severe infection may be treated with one of the *β*-lactam-*β*-lactamase inhibitors (ampicillin-sulbactam, 1.5 g IV every 6 hours, or piperacillin-tazobactam, 3.375 g IV every 6 hours). Alternatively, clindamycin (900 mg IV every 8 hours) with a fluoroquinolone (ciprofloxacin, 400 mg IV every 12 hours, or levofloxacin, 500 mg IV every 24 hours) may be given.

**SEXUALLY TRANSMITTED DISEASES**

**URETHRITIS AND CERVICITIS**

Dual therapy with ceftriaxone (250 mg intramuscularly [IM] once) for coverage of penicillin and fluoroquinolone-resistant *Neisseria gonorrhoeae* and azithromycin (1 g PO) for *Chlamydia trachomatis* is recommended. The more recently
recognized *Mycoplasma genitalium* is also covered by azithromycin. For patients with severe penicillin allergy, 2 g of azithromycin PO may be given.

**SYPHILIS**

The treatment of syphilis has remained essentially unchanged since the 1940s, when penicillin was introduced. Today, penicillin remains the drug of choice for syphilis.

For primary, secondary, and early latent (<1 year) syphilis, a single injection of benzathine penicillin G (2.4 million units IM) is recommended. Patients with severe penicillin allergy may be treated with doxycycline (100 mg PO twice daily) for 14 days.

Late latent syphilis, syphilis of unknown duration, and tertiary syphilis are treated with three injections, 1 week apart, of benzathine penicillin G (2.4 million units IM). Doxycycline (100 mg PO twice daily) for 4 weeks is an alternative.

Neurosyphilis requires intravenous administration of aqueous crystalline penicillin G (4 million units every 4 hours for 10 to 14 days).

**CHANCROID**

Fortunately, the painful genital ulcers of chancroid, caused by the difficult to detect *Haemophilus ducreyi*, have declined in prevalence in the United States. Single-dose therapy is recommended with azithromycin (1 g PO) or ceftriaxone (250 mg IM).

**EPIDIDYMIS AND PROSTATITIS**

Men 35 years of age and younger who have either epididymitis or prostatitis must be treated with antimicrobial agents that target the sexually transmitted pathogens *N. gonorrhoeae* and *C. trachomatis* with ceftriaxone (250 mg IM once) and doxycycline (100 mg PO twice daily for 10 days). In contrast, men older than 35 years are more likely to be infected with Enterobacteriaceae, and fluoroquinolones are recommended; that is, ciprofloxacin (500 mg PO twice daily) or levofloxacin (750 mg PO every day) for 10 to 14 days.

**SUGGESTED READINGS**

Within the broad scope of emergency medical treatment, wound repair plays a prominent role. Wounds occur in all types of people—from the youngest toddlers to frail elderly grandparents. In contrast to many other conditions requiring treatment in the emergency department (ED), wounds (typically) occur independently of patients’ other medical issues. However, each patient’s unique substrate for healing is one of the two most significant factors affecting satisfactory wound healing. The second significant consideration is the characteristics of the wound itself.

Approximately 12 million wounds are treated in EDs in the United States each year. Data on the true incidence of wounds are limited because many are thought to be treated away from the ED or urgent care setting. Of individuals with wounds seen in the ED, the majority are men. Wounds can clearly occur anywhere on the body, but lacerations on the upper extremities, head, and neck constitute the majority of cases encountered in EDs.

Skin, the largest organ in the body, has numerous functions, most prominently heat exchange, prevention of infection, and provision of a tactile interface with the environment. The layers of skin—epidermis, dermis, and connective tissue—all play different roles in wounds and healing. The thickest and most important layer, the dermis, serves as structural integument, supports conveyance of nutritional and waste products, and contains cutaneous nerves (Fig. 186.1).

Disruption of the skin may be caused by an infinite number of means, from simple cutlery accidents to industrial mishaps or intentional violence. Wounds that disrupt the full depth of skin are fundamentally different from those that affect only the superficial layers. Wounds that affect merely the epidermis may typically be cleansed and dressed appropriately with less concern for complications. However, it is imperative to assess seemingly superficial wounds in a diligent manner to ensure that more significant injuries are absent.

After injury, a continuum of coagulation, hemostasis, inflammation, tissue formation, and tissue remodeling quickly ensue. Each of these steps is influenced by the patient’s condition and the clinician’s wound repair skills. Clearly achieving hemostasis is a primary concern for wound repair, both to prevent exsanguination and to allow adequate visualization of the wound, as well as closure of it. Any delay in wound closure allows the later three steps of inflammation, tissue formation, and remodeling to proceed naturally, which will probably result in skin that is functional but scarred.

The aesthetic qualities of a scar are influenced by its thickness, color, and height or degree of depression. Thickness is most dependent on the width of the healing wound and on whether additional granulation tissue is necessary to fill gaps (as in secondary intention). The height of a scar is altered by the alignment and apposition of the healing skin edges, as well as by tensile and shear forces across the wound and the amount of inflammation preceding the formation of scar tissue. The increased height of a hypertrophic scar is the result of...
example, a 4-cm linear laceration on the arm of a healthy 18-year-old patient has a different prognosis than the same wound on the shin of a 73-year-old diabetic patient with peripheral vascular disease (Box 186.1).

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

**PATIENT EVALUATION**

With an infinite variety of medical conditions and circumstances requiring ED management, each patient has a unique environment for wound healing. Hosts also change over time: thinning of the dermis, varying degrees of vascular compromise, increased likelihood of fractures, and medication use. Assessment of patient status before the injury, as well as prediction of the patient’s capacity for healing, is important before initiating wound repair.
